includes a third-generation cephalosporin plus metronidazole. In postsurgical abscesses, vancomycin or an antistaphylococcal penicillin should be used to cover methicillin-resistant *S. aureus* (MRSA) (2,5,10,12).

TABLE 183.1
Choices of Empiric Antibiotics Based on the Suspected Source of the Abscess and Pathogens Involved

Source	Anatomic Location	Causative Agent	Treatment[a]
Penetrating trauma	Depends on site	*S. aureus* *Clostridium* sp. Enterobacteriaceae	Cefotaxime + metronidazole
Postoperative	Variable	*S. epidermis* and *S. aureus* Enterobacteriaceae *Pseudomonas* sp.	Vancomycin + ceftazidime
Paranasal sinuses	Frontal lobe	Aerobic & anaerobic *Streptococcus* sp. *Hemophilus* sp. Anaerobes (*Bacteroides* sp., *Fusobacterium* sp.)	Penicillin G + cefotaxime + metronidazole
Otogenic	Temporal lobe Cerebellum	*Streptococcus* sp. Enterobacteriaceae *Pseudomonas aeruginosa* *Bacteroides* sp.	Penicillin G + cefotaxime + metronidazole
Hematogenous	Multiple lesions, often in the MCA territory	Depends on source Endocarditis Intra-abdominal Lung abscess	Nafcillin + metronidazole + cefotaxime

MCA, middle cerebral artery.
[a]The intravenous dosages for adults of these antibiotics are as follows:
Cefotaxime: 1–2 g q4–8h (max 12 g/d)
Ceftazidime: 1–2 g q4–8h (max 12 g/d)
Metronidazole: 500 mg q6h
Nafcillin: 2 g q4h
Penicillin G: 2–4 million units q4h
Vancomycin: 1 g q12h

DISPOSITION

All patients diagnosed with a brain abscess in the ED require admission to the hospital and immediate neurosurgical consultation. If a neurosurgeon is not available, arrangements should be made for transfer to a neurosurgical center after stabilization. Young persons, patients without underlying disease, and patients without neurologic deterioration or mental status changes have a better prognosis. With early diagnosis, advanced neuroradiologic imaging, and rapid treatment, mortality is $<30\%$, but patients presenting with signs of herniation have mortality $>50\%$ (2,5). Persistent neurologic deficits, including seizure, intellectual or behavioral impairment, and motor deficits, are seen in 30% to 55% of patients (5).

CRANIAL EPIDURAL AND SUBDURAL SPACE INFECTIONS

Intracranial subdural empyema and cranial epidural abscess are rare but life-threatening intracranial suppurative infections. Subdural empyema accounts for 15% to 25% of focal intracranial infections, and cranial epidural abscess is much less common. Subdural empyema is a disease of teenagers and young adults, with 70% of cases occurring in the second and third decades of life (13). Epidural abscess rarely occurs in young children and has been reported in patients from ages 12 to 68 years. Both conditions exhibit a 3:1 male-to-female predominance (5,13).

Subdural empyema forms between the dura mater and arachnoid mater, and cranial epidural abscess forms outside the dura mater. Both entities share a similar pathogenesis and etiology, and the two infections can coexist. Subdural empyema is typically a complication of sinusitis, and less frequently of otitis media or mastoiditis. Less frequent is the spread of organisms through Haversian canals in bone as a complication of osteomyelitis (12,13). Other causes include cranial osteomyelitis, mastoiditis, otitis media, head trauma, cranial surgery, ventriculoperitoneal shunt, halo traction pins, orbital infections, and chronic subdural hematoma (5,14). In children, bacterial meningitis is the most common predisposing condition (2).

Multiple pathogens are typically responsible for these infections and are dependent on the initial site of infection. Aerobic, microaerophilic, and anaerobic streptococci, including *S. milleri* and *Streptococcus anginosus,* are common organisms with an otorhinogenic origin. *S. aureus* and coagulase-negative staphylococci are found in sinus, otic, postoperative, and posttraumatic cases, with as many as 46% of postsurgical subdural empyemas caused by *S. aureus* (15). Gram-negative bacilli can usually be seen in otic and posttraumatic sources. Polymicrobial infections are common and a sterile culture may be found in 20% to 30% of cases. In children, the most common causative agents are those responsible for the underlying meningitis (2,5,12,13,15).

CLINICAL PRESENTATION

The clinical presentation of subdural empyema is fever, headache, and nuchal rigidity. The nonspecific symptoms of a sinus or ear infection, fever, and malaise rapidly progress to severe headache and meningismus (13). The headache, present in 90% of cases, is focal, but becomes more generalized. Nausea and vomiting are common. Varying degrees of encephalopathy can be seen, ranging from mild confusion to coma. Third and sixth cranial nerve palsies are seen rarely. Seizures, however, have been reported in 50% of patients (13,14). Postoperative and posttraumatic subdural empyemas have a very indolent course caused by slow accumulation of fluid. Headache is often absent and the disease course is more benign (5).

The presentation of epidural abscess is more insidious. Symptoms can take weeks to months to develop. Patients often present with a long history of nonspecific symptoms without focal signs or mental status changes. Once the fluid mass reaches critical size, nausea, vomiting, headache, drowsiness, and lethargy occur. Focal neurologic signs, seizure, and coma do not occur unless the infection spreads to the subdural space, or cerebral herniation occurs. A patient with an epidural abscess involving the petrous bone may present with pain in the distribution of the fifth cranial nerve, and a sixth cranial nerve motor palsy (Gradenigo syndrome) (16).

DIFFERENTIAL DIAGNOSIS

The initial presentation of subdural empyema and epidural abscess is similar to other intracranial processes. Meningitis, brain abscess, subdural hematoma, subarachnoid hemorrhage, herpes encephalitis, venous sinus thrombosis, and tumor should be considered.

ED EVALUATION

History and physical examination should focus on finding potential sources of infection. A detailed neurologic examination should be performed. Routine laboratory evaluation is of limited value. The white blood cell count may be only mildly elevated and is often normal. The sedimentation rate may be elevated if osteomyelitis is present. Cerebral spinal fluid analysis is usually not helpful and is relatively contraindicated because of the risk of herniation (13).

CT scanning with IV contrast remains the mainstay of ED diagnosis for both subdural empyema and cranial epidural abscess, yet the diagnostic procedure of choice is MRI with gadolinium (13). Subdural empyema reveals a crescent-shaped, hypodense fluid collection in the subdural space with displacement of the arachnoid. A mass effect is common and an enhancing rim may be seen. Epidural abscess appears as a poorly defined, lentiform, extra-axial area of low or intermediate density. These entities can be easily missed by CT, given the proximity of the cranial vault, so MRI should be used when CT scanning is negative in the face of high clinical suspicion (13,17).

KEY TESTING

- Routine laboratory evaluation is of low yield.
- MRI and CT scanning are the studies of choice, with MRI considered the diagnostic test of choice for both disease processes.

ED MANAGEMENT

Once the diagnosis is made, immediate neurosurgical consultation is required. If signs of impending herniation are present, temporizing measures must be employed.

Antibiotic coverage should begin in the ED. The choice of antibiotic should be tailored to the suspected source until culture results are available. A scheme for antibiotic selection is outlined in Table 183.1.

DISPOSITION

All patients require admission. If neurosurgical services are not available, the patient, once stabilized, should be transferred to an appropriate center with available neurosurgical services. Patients with an isolated cranial epidural abscess have an excellent prognosis. Most recover with good neurologic outcome. The mortality for subdural empyema ranges from 9% to 48% (18). Of those patients who survive, 15% to 44% have a persistent neurologic deficit

(seizure disorder, hemiparesis, aphasia). Outcome is directly related to advanced patient age, degree of encephalopathy present, and delay to appropriate therapy (18).

SPINAL EPIDURAL ABSCESS

SEA, although still a rare entity, has doubled in incidence in the past 20 years, with 1.2 to 3 cases per 10,000 patients. This increase is likely due to an aging population, increased use of spinal instrumentation, and the increase in intravascular drug use (19,20). The most important risk factors are diabetes, trauma (e.g., spinal instrumentation), intravenous drug use, alcoholism, advanced age, and an immunocompromised state. Diabetes remains the single most important risk factor, and presents in 15% to 33% of cases (19). Bacteria gain access by hematogenous dissemination in 50% of cases, by contiguous spread in 33% of cases, and in the remaining percentage the source is not identified (20). The most frequently isolated organism is *S. aureus,* with up to 40% being the methicillin-resistant strain. *Streptococcus* sp.*, Escherichia coli, Pseudomonas* sp.*, Klebsiella* sp.*, Acinetobacter* sp., and *Mycobacterium tuberculosis* have also been found (19–21).

CLINICAL PRESENTATION

Back pain (75% of patients), fever (50%), and neurologic deficit (33%) are the classic triad of this disease process, but is only present in a minority of patients, 8% in one case report (20,21). There is a staging system detailing the progression of symptoms and physical findings: in stage 1 there is back pain at the level of the affected spine only; in stage 2 there is nerve-root pain radiating from the involved spinal area; in stage 3 there is motor weakness, sensory deficit, and bladder and bowel dysfunction; and stage 4, paralysis (20).

Irreversible paralysis remains the most feared complication of SEA, with delayed diagnosis one of the main culprits. About half of the cases are initially misdiagnosed (20), so considering this disease in your differential is of the upmost importance.

DIFFERENTIAL DIAGNOSIS

The presentation of an SEA is similar to many types of back pain. Other diagnoses to keep in mind when evaluating a patient with back pain include intervertebral disc herniation, metastatic epidural spinal cord compression, spinal epidural hematoma, and simple back strain. Separating these diagnoses requires a thorough history and physical examination. MRI and CT scan provide further information as to the cause of the back pain.

ED EVALUATION

The diagnosis of SEA is suspected on the basis of clinical findings and supported by laboratory data and imaging studies. Leukocytosis is present in two-thirds of patients, and inflammatory markers (erythrocyte sedimentation rate [ESR] and C-reactive protein [CRP]) are almost always elevated, with 100% sensitivity for ESR noted in one study (22). Bacteremia is noted in 60% of patients, so blood cultures should also be utilized (20). CSF analysis should be entertained with caution, as there is a risk of spread of infection if the needle traverses the abscess.

Contrast CT of the spine is better than noncontrast imaging for identifying an abscess, but is still inferior to MRI. MRI is the most useful study for demonstrating an abscess with sensitivity reported to be between 90% and 100% (19–21,23). MR images also demonstrate discitis and osteomyelitis when present, which coexist with up to 80% of patients (20).

KEY TESTING

- Inflammatory markers (ESR and CRP) help with the diagnosis of SEA (22).
- MRI and CT scanning remain the studies of choice for this disease processes, with MRI (preferably with gadolinium) considered the diagnostic test of choice if available (19–21,23).

ED MANAGEMENT

Surgery and antibiotics are the mainstays of therapy. Antibiotics should be started as soon as the diagnosis is established. Appropriate antibiotic choices should provide coverage against staphylococci (typically with vancomycin for MRSA coverage), and gram-negative bacilli with a third- or fourth-generation cephalosporin (e.g., ceftazidime or cefepime). Antibiotics are usually continued for 6 weeks (19,20).

CRITICAL INTERVENTIONS

- Suspect CNS abscess or other suppurative infection in high-risk patients with headache, neck pain, or back pain and order CT or MRI.
- Administer antibiotics in the ED.
- Obtain neurosurgical consultation (or orthopedic spine consultation as appropriate).

DISPOSITION

All patients with an SEA require admission to a neurosurgical or spinal orthopedic surgery service. If these are not available, the patient should be stabilized, should have antibiotics started, and should be transferred to an appropriate center. Neurologic deficits for greater than 48 hours, immunocompromised patients, involvement of the thoracic spinal cord, and MRSA as the causative organism all worsen the prognosis for a complete recovery.

Common Pitfalls

- Failure to suspect a suppurative CNS infection in patients presenting with headache, neck pain, or back pain
- Inappropriate antibiotic selection because the probable origin of the infection was not considered
- Delay in initiating treatment for increased intracranial pressure and obtaining neurosurgical consultation

CHAPTER 184 Sexually Transmitted Diseases

Diane M. Birnbaumer and Jaime M. Jordan

Sexually transmitted diseases (STDs) are commonly encountered in the emergency department and primary care settings. The United States has one of the highest rates of STDs in the industrialized world, estimated to be 50 to 100 times higher than other nations, with approximately 110 million total infections and nearly 20 million new cases per year, costing the US healthcare system 16 billion dollars a year in direct medical costs (1–3). The true prevalence and incidence is likely higher, as it is estimated that reported cases of STDs represent only 50% to 80% of reportable STD infections in the United States (4). Diagnosis and treatment is important to prevent future complications of untreated disease, such as infertility, and to prevent the further spread of infection.

The history and physical examination are paramount in diagnosing STDs. Important aspects of the history include symptoms and their duration, history of previous STDs, timing and types of sexual contacts, use of contraceptive agents or devices and, in women, menstrual history. A thorough examination of the genital area is important, with emphasis on observation for lesions and for the presence of discharge. In addition, examination for lymphadenopathy (local and systemic), a joint examination (if the patient is symptomatic), and examination of the skin for rashes and lesions are critical.

Most STDs can be divided into ulcerative diseases (those presenting with ulcers and/or inguinal adenopathy) and

nonulcerative diseases (those presenting with urethral, cervical, or vaginal discharge). **Tables 184.1** and **184.2** list the differential diagnoses of both ulcerative and nonulcerative genital complaints.

TABLE 184.1
Differential Diagnosis of Ulcerative Sexually Transmitted Diseases

Herpes	Scabies
Syphilis (primary)	Pyoderma
Chancroid	Trauma
Lymphogranuloma venereum (LGV)	Excoriations
Granuloma inguinale (Donovanosis)	Behçet disease
Molluscum contagiosum	Drug reaction
Genital warts	Yeast infection
Pediculosis	

TABLE 184.2
Differential Diagnosis of Nonulcerative Sexually Transmitted Diseases

Gonorrhea
Chlamydia
Nongonococcal urethritis
Secondary/tertiary syphilis
Candidal vaginitis
Trichomonas
Bacterial vaginosis

ULCERATIVE SEXUALLY TRANSMITTED DISEASES

Patients may present with complaints of an ulcer or sore on or adjacent to the genitalia. Although there are nonsexual causes of genital ulcers, patients presenting with these lesions should be considered to have a sexually transmitted infection until proven otherwise. Infections presenting with genital lesions may be difficult to distinguish from one another based on examination alone, so history is of particular importance in determining the cause of the

lesion. Key points in the history include the characteristics of the lesion(s) such as the type of initial lesion (vesicle or papule), whether the lesion is single or multiple, is painful or nontender, has regular or irregular borders, or is indurated or soft. If adenopathy is part of the presentation, determine whether it is or is not painful, whether it is unilateral or bilateral, and whether it is fluctuant (Table 184.3).

TABLE 184.3
Characteristics of Ulcerative Sexually Transmitted Diseases

Disease	Nature of Genital Ulcer	Incubation Period	Painful	Inguinal Adenopathy	Diagnostic Tests
Syphilis	Indurated, sharply demarcated, with red, smooth base; heals spontaneously	9–90 d; average 2–3 wks	No	Firm rubbery nodes; nontender	Dark-field examination; serologic
Herpes simplex	Multiple, small grouped vesicles on a red base, which form shallow ulcers; may coalesce; resolve spontaneously but recurrence common	2–7 d	Yes	Bilateral, firm, tender	PCR, culture, serology: nontreponemal (VRDL, RPR) & treponemal (FTA-ABS, TP-PA)
Chancroid	Irregular, sharply demarcated borders with undermined edges, shallow, often multiple	3–6 d	Yes	Unilateral, most common; overlying erythema, fixed and tender, suppuration possible	Culture
Lympho-granuloma venereum	Usually single lesion, papule or ulcer, transient, frequently not noticed	5–21 d	No	Unilateral, most common; firm, tender, matted fixed May suppurate or form fistulas	Culture, direct immunofluorescence, nucleic acid testing of tissue (swab/aspirate); LGV complement fixation (serology)

Treatment is often necessary before test results are available; treatment decisions should be based on the most likely diagnosis. The most common ulcerative diseases in the United States are, in order of incidence, herpes, syphilis, and, in rare outbreaks, chancroid (5). Any patient with an ulcerative lesion should have herpes simplex virus (HSV) testing and syphilis serology sent and, as ulcerative diseases increase the risk of HIV infection, all patients should also be offered HIV testing.

HERPES GENITALIS

Genital herpes is an STD caused by the HSV type 2 (HSV-2) and, less commonly, type 1 (HSV-1). Herpes lesions are by far the most common cause of genital ulceration owing to infection in developed countries, with an estimated 775,000 new cases annually and more than 50 million persons infected in the United States (2,6). Although herpes infection usually does not often produce serious sequelae in nonpregnant patients, genital herpes infection plays a major role in

the spread of HIV as persons infected with genital herpes are more susceptible to HIV infection, and herpes infection can make HIV positive persons more infectious.

CLINICAL PRESENTATION

In immunocompetent individuals, the severity of presentation of symptomatic genital herpes depends on whether it is the patient's first infection with a herpes virus or whether the patient has had prior herpes infection (genital or labial). Primary herpes infection is the initial infection in a patient without circulating antibodies to either HSV-1 or HSV-2. Clinical presentations can be highly variable. After an incubation period of 2 to 7 days, patients often develop systemic symptoms, including low-grade fever, malaise, headache, and myalgias. Grouped, multiple small vesicles on an erythematous base appear on the genitalia and develop into painful, shallow ulcers. The severity of local symptoms reaches its peak between 8 to 10 days, gradually receding over the second week of illness. The lesions of the primary episode are generally present for 2 to 4 weeks until complete healing occurs. Patients may also develop adenopathy, most often during the second or third week. The nodes are usually bilateral, slightly enlarged, nonfluctuant, and mildly tender. Severe external dysuria, another common symptom, is more often seen in women and may lead to urinary retention. Urinary retention can also occur as a consequence of sacral radiculomyelopathy, which may also cause constipation and sensation changes in the lumbosacral distribution. Other uncommon complications of primary herpes infection include aseptic meningitis and transverse myelitis.

Patients with circulating antibodies to HSV-1 who acquire genital HSV-2 infection tend to have a less dramatic course, and their infection resembles that of a recurrence in a patient with known genital herpes.

Herpes is a lifelong infection; the virus remains latent and recurs in 60% to 90% of patients. The symptoms of recurrence are distinctly milder than during the primary infection. Systemic symptoms are rare, and patients typically have fewer lesions with a shorter time to complete healing. Prodromal symptoms occur in more than half of

the patients who experience recurrence, including localized paresthesias, itching, burning, or hypersensitive skin at the site of subsequent lesions. Virus is shed from both primary and recurrent lesions for several days after ulcerations or erosions first appear. It is also important to note that intermittent asymptomatic viral shedding can occur and lead to the transmission of the disease even in the absence of genital lesions.

ED EVALUATION

It is tempting to make the diagnosis of genital herpes based on clinical suspicion, but clinical diagnosis is neither sensitive nor specific, and confirmatory testing is recommended, especially in women of childbearing age. The preferred tests for genital herpes are cell culture or polymerase chain reaction (PCR). The sensitivity of viral culture is low and declines rapidly as lesions begin to heal. False-negative results are common owing to improper collection or transport, and results are reported in 2 to 7 days. PCR assay for HSV DNA is more sensitive than culture and is considered the test of choice for detecting HSV central nervous system infection. Cytologic detection of herpes virus (Tzanck prep or PAP smear) is insensitive and nonspecific and should not be used. Serologic, type-specific testing based on HSV glycoproteins can provide results with sensitivities of 80% to 90% and specificities of more than 96%. These tests may give false-negative results, especially at early stages of infection.

KEY TESTING

- PCR assay for HSV DNA
- HIV
- Serologic test for syphilis (VDRL/RPR)

ED MANAGEMENT

Genital herpes is a lifelong infection without a definitive cure, but skin lesions are self-limited and heal spontaneously unless secondarily infected. Systemic antiviral drugs (acyclovir,

valacyclovir, and famciclovir) are the mainstay of therapy (7), as they partially control the symptoms and signs of herpes, shorten the duration of symptoms, decrease the duration of shedding, and can abort recurrence episodes. Table 184.4 outlines the different treatment regimens for genital herpes. Unfortunately, these drugs neither eradicate latent virus nor affect the risk, frequency, or severity of recurrences after the drug is discontinued. Suppressive therapy can reduce the frequency of genital herpes recurrences by 70% to 80%, and studies show up to 6 years of acyclovir use and 1 year of continuous use of the other agents is safe (7). Topical antivirals offer minimal clinical benefit and their use is discouraged (7). Other goals of treatment are symptomatic treatment and include pain control and genital hygiene.

TABLE 184.4
Treatment Guidelines

Disease	Recommended Treatment Regimen	Alternative(s)
Chlamydia	Azithromycin 1 g PO in a single dose or doxycycline 100 mg PO BID × 7 d	Erythromycin base 500 mg PO QID × 7 d or Ofloxacin 300 mg PO BID × 7 d or Levofloxacin 500 mg PO QD × 7 d or Erythromycin ethylsuccinate 800 mg PO QID × 7 d
Gonorrhea, urethral, cervical, or rectal	Ceftriaxone 250 mg IM × 1 plus either azithromycin 1 g orally once OR doxycycline 100 mg orally twice a day for 7 d	
Gonorrhea, conjunctival	Ceftriaxone 1 g IM once	
Gonorrhea, disseminated	Ceftriaxone 1 g IM or IV once daily	
Herpes simplex, first episode	Acyclovir 400 mg PO TID × 7–10 d or Acyclovir 200 mg PO 5 times daily × 7–10 d or Famciclovir 250 mg PO TID × 7–10 d or Valacyclovir 1 g PO BID × 7–10 d	
Herpes simplex, recurrent	Acyclovir 400 mg PO TID × 5 d or Acyclovir 800 mg PO TID/d × 2 d or Acyclovir 800 mg PO BID × 5 d or Famciclovir 125 mg PO BID × 5 d or Famciclovir 500 mg PO × 1, then 250 mg PO BID × 2 d Famciclovir 1,000 mg PO BID × 1 d Valacyclovir 500 mg PO BID × 3–5 d Valacyclovir 1 g PO daily × 5 d	
Herpes simplex, suppressive	Acyclovir 400 mg PO BID or Famciclovir 250 mg PO BID or Valacyclovir 500 mg PO QD or Valacyclovir 1 g PO QD	
Syphilis, primary, and secondary	Benzathine penicillin G 2.4 million units IM × 1	Doxycycline 100 mg PO BID × 14 d Tetracycline 500 mg PO QID × 14 d
Syphilis, latent	Benzathine penicillin G 2.4 million units q wk × 3	
Syphilis, tertiary (absence of signs of neurosyphilis)	Benzathine penicillin G 2.4 million units q week × 3	Procaine penicillin 2.4 million units IM daily + Probenecid 500 mg PO 4 times daily × 10–14 d (use only if compliance can be ensured)
Syphilis, tertiary (presence of neurosyphilis)	Aqueous crystalline penicillin G 18–24 million units/d IV administered as 3–4 million units IV q4h or continuous infusion × 10–14 d	
Chancroid	Azithromycin 1 go PO × 1 or ceftriaxone 250 mg IM × 1 or ciprofloxacin 500 mg PO BID × 3 d or erythromycin base 500 mg PO TID × 7 d	
Lymphogranuloma venereum	Doxycycline 100 mg PO BID × 21 d	Erythromycin base 500 mg PO QID × 21 d

All patients should be counseled to refer partners for evaluation and that the disease is transmissible even when asymptomatic. Women of childbearing age must inform their doctor of their history of genital herpes when becoming pregnant. Women who acquire herpes during pregnancy have a significantly increased risk of fatal neonatal herpes infections, and high rates of neonatal morbidity have been reported in association with both symptomatic and asymptomatic primary infections acquired late in pregnancy. Consultation with the patient's primary care doctor is recommended before starting any treatment regimen in pregnant patients, as the safety of systemic acyclovir, valacyclovir, and famciclovir therapy in pregnant women has not been established.

SYPHILIS

Syphilis is a disease caused by the spirochete *Treponema pallidum* and is capable of involving any organ of the body. Transmission occurs primarily during sexual contact, and exposure to moist skin or mucous membranes is necessary for the infection to occur. Since the year 2000, the incidence of this infection has been increasing, with an estimated 55,000 new cases annually (5).

CLINICAL PRESENTATION

The natural history of untreated syphilis infection is described in four stages.

1. Primary. The incubation period varies from 9 to 90 days, with an average of 2 to 4 weeks. The primary lesion is a chancre, which occurs at the point of inoculation. Patients may note that before ulcerating, the lesion may have started as a papule. The chancre is characteristically painless, usually single, and has a smooth, slightly raised edge with sharply defined borders and an indurated base. A few days after appearance of the chancre, if the primary lesion is on the genitals, patients may develop unilateral or bilateral inguinal lymphadenopathy, which is usually painless and is not a prominent feature of the infection. The chancre is indolent and, if not treated, usually persists 2 to 6 weeks before spontaneously healing, and the infection progresses to the secondary stage.
2. Secondary. The average interval between the appearance of the primary chancre and secondary lesions is 5 to 8 weeks. Constitutional flu-like symptoms are common, including low-grade fever, malaise, headache, sore throat, arthralgias, and generalized lymphadenopathy. Patients typically develop a macular rash, which starts on the trunk and spreads to the abdomen, shoulders, and limbs, evolving into a symmetric papulosquamous rash that may resemble pityriasis rosea. The rash often involves the palms and soles with maculopapular lesions. Patients may also develop condyloma lata: hypertrophic, broad-based papules with flat moist tops, most common on the labia, around the anus, and between the buttocks. Lesions may be seen on the tongue and are called mucous patches. When

adenopathy is present, it may be anywhere on the body, and the nodes are discrete, nontender, and rubbery. If untreated, this stage also resolves spontaneously.

3. Latent. This stage begins when secondary symptoms disappear. Patients are asymptomatic during the latent phase, and disease is detected solely by serologic testing. Latent syphilis acquired within the preceding year is referred to as early latent syphilis; all other cases of latent syphilis are either late latent syphilis or latent syphilis of unknown duration.
4. Tertiary. Cardiovascular and central nervous system symptoms predominate in this stage. The symptoms occur 3 to 4 years or later after the primary stage but may be seen earlier in immunocompromised patients such as those with HIV infection. Specific manifestations include meningitis, peripheral neuropathy (tabes dorsalis), thoracic aortic aneurysms, and gummatous lesions of the mucous membranes.

ED EVALUATION

Dark field examination and direct fluorescent antibody tests of lesion exudates or tissue are the definitive methods for diagnosing early (primary) syphilis. However, the sensitivity is only approximately 80%, and lack of availability of dark field microscopy and trained personnel limit the use of this technique (8).

Currently, serologic testing is the mainstay of diagnosis for secondary, latent, and tertiary syphilis. Serologic tests are divided into nontreponemal and treponemal tests, and both are required for definitive diagnosis. Nontreponemal tests measure nonspecific antibodies found in the serum of patients with syphilis. These tests include the venereal disease research laboratory (VRDL) and rapid plasma reagin (RPR) tests, and they vary in their sensitivity based on the stage of syphilis. Nontreponemal tests are positive about 2 weeks after the appearance of the primary lesion. As the results are quantitative, the titers can be followed to determine the response to treatment. However, care must be taken to use the same test and preferably the same laboratory. The antibodies reach their highest levels during secondary syphilis, during which time the sensitivity of

nontreponemal tests approaches 100%. These tests are not specific for *T. pallidum,* however, so false-positive tests do occur. Syphilis is confirmed with the treponemal tests, fluorescent treponemal antibody-absorption (FTA-ABS) or microhemagglutination assay T. pallidum (MHA-TP), which measure specific antibodies formed by the host in response to infection with *T. pallidum.* Treponemal test antibody titers should not be used to assess treatment response (7). Patients suspected of having neurosyphilis typically have CSF-VDRL performed, which is highly specific, but not sensitive.

KEY TESTING

- Serologic test for syphilis (VDRL or RPR)
- HIV

ED MANAGEMENT

For primary and secondary syphilis, benzathine penicillin G 2.4 million units IM × 1 is the treatment of choice (7); see Table 184.4 for alternative treatment regimens and for treatment of latent and tertiary syphilis. Sexual partners within the last 90 days should be tested but treated presumptively; partners after more than 90 days should be evaluated and treated if indicated. If serologic results are not available or follow-up is uncertain, these patients should also be treated presumptively. All patients should be referred for HIV testing. Patients should be referred for re-examination clinically and serologically 6 months and 12 months after treatment, as RPR and VDRL should become nonreactive after successful treatment. A fourfold or greater decrease in titers after 6 months correlates with decreasing antibody levels and successful treatment. Parenteral penicillin G is the only therapy with documented efficacy for syphilis during pregnancy. Because congenital syphilis can be devastating, pregnant women with syphilis in any stage who report penicillin allergy should be desensitized and treated with penicillin (7).

CHANCROID

The gram-negative bacterium *Haemophilus ducreyi* is the causative agent of chancroid. The infection is characterized by painful genital ulcerations and frequent bubo formation. These fluctuant nodes can spontaneously rupture, leading to the formation of inguinal ulceration and excavation. Though common in developing countries (9), the disease is rare in the United States, with usually <100 total reported to the Centers for Disease Control (CDC) annually (5). Infections can occur in small outbreaks in susceptible populations. In addition, as *H. ducreyi* is difficult to culture, the condition may be substantially under-diagnosed.

CLINICAL PRESENTATION

The incubation period is 3 to 6 days, after which a small, tender red papule or pustule appears at the site of inoculation. The papule rapidly progresses to an ulcer, characterized by sharply demarcated edges and sloughing bases, often with necrotic exudates. Multiple lesions are common and lesions may coalesce. About 1 week after the ulcers develop, about half of patients will develop lymphadenitis, which is typically unilateral, painful, and fluctuant. The overlying skin is often thinned and erythematous, and suppuration and spontaneous rupture is common.

ED EVALUATION

Diagnosis is often based on clinical presentation and is often a diagnosis of exclusion, after ruling out other diseases such as herpes and syphilis. Presence of a fluctuant inguinal node in a patient with genital ulcers strongly suggests the diagnosis. Confirming the diagnosis of chancroid requires identifying the organism *H. ducreyi.* This organism is difficult to grow and requires a special medium that is frequently not available. A probable diagnosis can be made if all of the following criteria are met: (a) the patient has one or more painful genital ulcers, (b) the patient has no evidence of *T. pallidum* infection by dark-field examination or serologic testing, (c) the clinical presentation, appearance of genital ulcers, and regional lymphadenopathy are typical for chancroid, and (d) a test for HSV performed on the ulcer exudates is negative (7).

KEY TESTING

- PCR assay for HSV DNA
- HIV
- Serologic test for syphilis (VDRL or RPR)

ED MANAGEMENT

Treatment is curative. The CDC has four recommended regimens (7); see Table 184.4 for more treatment options. All patients should be referred for HIV and other STD testing. About 10% of patients who have chancroid acquired in the United States are coinfected with *T. pallidum* or HSV, and chancroid is a risk factor for HIV transmission. Sex partners during the 10 days preceding the patient's onset of symptoms should be examined. Patients should be referred for re-examination 3 to 7 days after initiation of therapy to confirm response to treatment. The length of time required for complete healing varies by the size of ulcer; advanced disease can lead to scarring despite treatment.

LYMPHOGRANULOMA VENEREUM

Lymphogranuloma venereum (LGV) is characterized by a transient genital lesion followed by lymphatic involvement in the genitalia, pelvic area, and rectum that can lead to chronic complications such as elephantiasis. It is caused by specific serotypes of *Chlamydia trachomatis*. This disease is prevalent in many tropical countries but is rare in the United States, usually occurring in small isolated outbreaks.

CLINICAL PRESENTATION

The incubation period is 3 days to 3 weeks. The primary lesion is a small, painless ulcer that is transient and may go unnoticed. The disease usually presents in the secondary stage, when regional lymphadenitis appears, usually 7 to 30 days after the disappearance of the primary lesion. The enlarged nodes are painful with overlying erythema. Inguinal lymphadenopathy, usually unilateral, may present with the "groove sign," enlargement of the glands above and

below the Poupart ligament. Patients may develop multiple draining sinuses or form a hard inguinal mass. Rectal exposure can lead to proctocolitis and if not treated early can result in colorectal fistulas and strictures. Elephantiasis may develop as a late complication owing to blockage of lymphatic channels.

ED EVALUATION AND MANAGEMENT

Diagnosis is often based on the clinical picture. Serologic testing for the specific serotype of chlamydia that causes LGV is available but is often a "send-out" test with results taking days to weeks to return. Tissue specimens (swab of ulcer or bubo aspirate) can also be tested for *C. trachomatis* by various methods. Other causes of inguinal lymphadenopathy and genital ulcers must be ruled out. Treatment cures the infection and prevents ongoing damage and potential complications. Doxycycline, 100 mg PO bid × 21 days is the preferred treatment. Erythromycin 500 mg PO qid × 21 days is an alternative regimen (7). All patients need referral for HIV testing, and sexual partners should be evaluated and treated.

KEY TESTING

- Culture, direct immunofluorescence, nucleic acid testing of tissue (swab or aspirate)
- HIV
- Serologic test for syphilis (VDRL or RPR)

NONULCERATIVE SEXUALLY TRANSMITTED DISEASES

Nonulcerative sexually transmitted diseases and infections are characterized by urethral or cervical discharge. The two most common nonulcerative STDs are chlamydia and gonorrhea; other causes include nongonococcal urethritis, candidiasis, bacterial vaginosis, and trichomoniasis. Clinical manifestations of infection with chlamydia and gonorrhea closely resemble each other, and the two commonly occur together. Therefore, it is usually not possible to distinguish the two diseases from one another clinically, and patients

are usually treated for both infections. Table 184.2 lists the differential diagnosis for nonulcerative STDs.

CHLAMYDIA

In the United States, chlamydia is one of the most commonly reported STDs, with nearly three million cases estimated annually (5). It is caused by *C. trachomatis* and can cause urethritis, proctitis, epididymitis, prostatitis, cervicitis, perihepatitis (Fitz-Hugh and Curtis syndrome) and pelvic inflammatory disease (PID) (see Chapter 130, "Pelvic Inflammatory Disease").

CLINICAL PRESENTATION

The incubation period is 1 to 3 weeks. Males usually present with symptoms of urethritis or epididymitis. Females, when symptomatic, may complain of symptoms ranging from dysuria to peritonitis. Frequently, women may have only vague, nonspecific complaints, including vaginal discharge or bleeding or abdominal or pelvic pain. Asymptomatic infection is common among both men and women; it is estimated that 75% of infected women and 50% of infected men have no symptoms (10,11). Sexually active adolescent females have a particularly high rate of infection, and chlamydial infection has been found in up to 10% of asymptomatic young women in family planning clinics (11,12). Infection in women can lead to PID, ectopic pregnancy, and infertility. It is estimated that 40% of women with untreated chlamydial infections will develop PID.

ED EVALUATION

Historically, the gold standard for diagnosis was cell culture. However, newer tests have better sensitivity and specificity than culture and are becoming the new gold standard. Nucleic acid amplification tests (NAATs) amplify nucleic acid sequences that are specific for the organism being tested and do not require the presence of viable organisms. NAATs have sensitivities that exceed that of culture (>90% vs. 60% to 80%, respectively), with specificities >99%. NAATs also are more sensitive than other nonculture tests (DNA probe testing, latex agglutination testing)

(13,14). These tests can be performed on both swabs (endocervical or urethral) and urine, although it is recommended to use endocervical swabs in women because the sensitivity is lower when performed on urine (13). Urine screening NAATs are adequate for males, especially when they are symptomatic; urethral swabs are generally not necessary (14). Culture is still preferred when an isolate is needed (e.g., in sexual abuse cases) and should be done in addition to NAATs in these cases (7).

KEY TESTING

- NAAT (Chlamydia and gonococcal) collected from endocervix, urethra, or urine.
- HIV
- Serologic test for syphilis (VDRL or RPR)

ED MANAGEMENT

Treatment consists of azithromycin 1 g PO × 1 dose or doxycycline 100 mg PO bid × 7 days (see Table 184.3 for alternative regimens) (7). Unless coinfection with gonococcal infection is definitively ruled out, the patient should be treated for both infections. Sexual partners need testing and treatment, and the patient should refrain from sexual intercourse until 1 week after completing treatment and after sex partners are treated.

GONORRHEA

Gonorrhea is an STD caused by the gram-negative diplococcus *Neisseria gonorrhoeae.* More than 800,000 new *N. gonorrhoeae* infections occur in the United States each year (5). Patients may present with infection of the urethra, rectum, cervical canal, pharynx, upper female genital tract, or conjunctival sac owing to the organism's predilection for infecting columnar or transitional epithelium.

CLINICAL PRESENTATION

The clinical presentation of localized disease varies depending on the gender of the patient and the site of infection. In men, acute urethritis is the most common presentation. Symptoms include dysuria and a penile discharge, starting within 1 to 14 days of exposure. Purulent urethral discharge and meatal erythema are found on physical examination in symptomatic males. Patients may also complain of testicular pain and swelling, with evidence of epididymitis, although this is an uncommon presentation.

Primary gonococcal infection in women is often asymptomatic; patients may have only vague complaints until complications such as PID have occurred. Symptoms, when they occur, are usually mild or nonspecific and can include vaginal discharge, abnormal vaginal bleeding, abdominal or pelvic pain, or urinary symptoms such as dysuria and frequency. Up to 20% of women with untreated gonorrhea develop PID, with symptoms including abnormal uterine bleeding, abdominal pain, and dyspareunia. Both symptomatic and asymptomatic cases of PID can result in tubal scarring that may lead to infertility or ectopic pregnancy (see Chapter 130 "Pelvic Inflammatory Disease"). Other presenting complaints may include Bartholin abscess or right upper quadrant pain secondary to perihepatitis (Fitz-Hugh and Curtis syndrome).

Other sites of primary infection include the oropharynx, anorectal area, and conjunctiva. Oropharyngeal gonococcal infection is often asymptomatic. Patients may have pharyngitis symptoms such as sore throat and exudative tonsillitis, but even without treatment, most cases are self-limited. Anorectal involvement is more common in homosexual men and heterosexual women. Like pharyngitis, anorectal infection is often asymptomatic. If patients develop symptoms, they may complain of rectal discomfort, anorectal pain, tenesmus, constipation, pruritus ani, and purulent or mucoid anal discharge or bleeding. On anoscopy, the mucosa appears friable, and a mucopurulent exudate may be present. Patients with conjunctival infection present with marked conjunctival erythema and purulent drainage (sometimes copious) and may have chemosis. If untreated, patients may develop vision-threatening complications such as corneal ulceration, endophthalmitis, and globe perforation.

Disseminated gonococcal infection, more common in women than men, results from gonococcal bacteremia. Patients present with systemic symptoms (fever, chills), joint complaints (arthralgias or arthritis, or tenosynovitis) and skin complaints (pustular rash, usually found on the peripheral extremities). The skin lesions are characteristically small tender papules that become pustular (described as necrotic pustules on an erythematous base), and most likely represent septic emboli to small blood vessels. If disseminated gonorrhea involves the joints, the arthritis usually presents with an acute monoarticular arthritis. Although the knee is most commonly involved, symptoms may also include elbows, ankles, wrists, and small bones of the hands and feet. The involved joint is erythematous and warm, may have an effusion, and is painful on passive and active range of motion. Other manifestations include hepatitis, myocarditis, endocarditis, and rarely, meningitis.

The definitive diagnosis of disseminated gonococcal arthritis is made by isolating gonococci from the blood or from an area reached hematogenously: synovial fluid, skin, or cerebrospinal fluid. Presumptive diagnosis is based on the appropriate clinical presentation combined with isolation of gonococci from a source site (urethra, cervix, pharynx, rectum).

ED EVALUATION

In symptomatic males or patients with gonococcal conjunctivitis, Gram stain of the discharge may have a sensitivity and specificity approaching 100% (10,15). The Gram stain is a quick means of diagnosing these cases, with results returned during the ED visit, and sensitivity and specificity of Gram stain are comparable to culture. In females and asymptomatic males, however, the Gram stain is less useful, with significantly decreased sensitivity.

The advantages to culture are that it is relatively inexpensive compared to NAATs, can assess antibiotic susceptabilities, and can be used on samples from any site. Culture is also the test of choice when the results will be used as evidence in legal investigations. On the other hand, accurate results may be limited by improper collection and handling of specimens. To maintain the viability of gonococcal

organisms, specimens should be inoculated directly onto the appropriate medium. Specimens from a sterile site, such as cerebrospinal fluid or synovial fluid, should be plated on nonselective medium such as chocolate agar. Specimens from areas high in normal bacterial flora (such as the cervix, urethra, rectum, or oropharynx) should be inoculated on selective media such as Martin Lewis agar. Immediately after plating, specimens should be incubated at 35°C to 36.5°C and transported to the laboratory in a carbon dioxide–enriched atmosphere (10).

As with chlamydia, NAATs have been shown to have good sensitivity and excellent specificity for detection of gonorrhea from endocervical, urethral, and urine samples. The sensitivity of NAATs is superior to that of culture (7) and endocervical swabs are more sensitive than urine specimens in women, so they are preferred (10,15).

KEY TESTING

- NAAT (Chlamydia and gonococcal) collected from endocervix, urethra, or urine
- HIV
- Serologic test for syphilis (VDRL of RPR)

ED MANAGEMENT

Due to changes in antibiotic resistance, the recommendations for treating gonorrhea were updated in 2012. Oral cephalosporins are no longer recommended. The current recommendation is to treat with a single IM dose of 250 mg of ceftriaxone plus either a 1-g oral dose of azithromycin or a 7-day course of doxycycline, 100 mg orally twice a day. Using the second agent was previously recommended to treat possible concurrent chlamydial infection, but now it is recommended for use in all cases of suspected gonorrhea as this second antimicrobial agent improves efficacy in treating gonorrhea. (see Table 184.4 for other alternatives) (7). Treatment with quinolones is no longer recommended in the United States because of recent increases in quinolone resistance (7). Patients should be instructed

that their partners need referral for evaluation, testing, and treatment. Patients should be instructed to avoid sexual intercourse until therapy is completed and until they and their sex partners are treated and no longer symptomatic. Patients should also be referred for HIV testing.

KEY TESTING

Disease	Diagnostic Tests
Ulcerative STD	
Chancroid	Culture
Herpes simplex	PCR, culture, serology: nontreponemal (VRDL, RPR) and treponemal (FTA-ABS, TP-PA)
Lymphogranuloma venereum	Culture, direct immunofluorescence, nucleic acid testing of tissue (swab or aspirate); LGV complement fixation (serology)
Syphilis	Dark field examination; serologic
Nonulcerative STDs	
Chlamydia	Culture, NAATs
Gonorrhea	Gram stain, culture, NAATs

NONGONOCOCCAL URETHRITIS

Nongonococcal urethritis (NGU) can occur in both men and women. Patients with NGU present with urethral discharge and dysuria or urethral pruritus. The etiology in many cases is unknown, although *C. trachomatis* is implicated as the most common cause; other organisms include *Ureaplasma* and *Mycoplasma.* Diagnosis is made by gram stain (>5 WBC per high-power field and no gram-negative diplococci), positive leukocyte esterase test on urinalysis, or more than 10 WBC per high-power field on urinalysis. All patients with urethritis should be evaluated for both gonorrhea and chlamydia. Treatment consists of azithromycin 1 g orally in a single dose or doxycycline 100 mg PO bid for 7 days (7). In women, other causes of vaginal discharge must be ruled out, including chlamydia, trichomoniasis, bacterial vaginosis, and candidiasis.

CRITICAL INTERVENTIONS

- Obtain syphilis serology on patients with ulcerative lesions.
- Refer all patients with STDs for HIV testing.
- Emphasize the importance of examination and treatment of sexual partners.
- Treat patients with nonulcerative STDs for both chlamydia and gonorrhea.

Common Pitfalls

- A significant number of patients with one STD are also infected with another.
- Treat patients with the expectation that they may not get follow-up. Observed single-dose therapy is the best guarantee of compliance with treatment.
- Syphilis, gonorrhea, chlamydia, and AIDS are reportable diseases in every state. HIV infection and chancroid are reportable in many states. Clinicians should be familiar with local reporting requirements and, if they are unsure, should seek advice from local health departments.

CHAPTER 185
Lyme Disease

Veronica Vasquez and Sean O. Henderson

Lyme disease (LD) is the most common vector-borne illness in North America. Also known as Lyme borreliosis, it is caused by the spirochete *Borrelia burgdorferi* and is primarily transmitted to humans by *Ixodes* ticks. Transmission of *B. burgdorferi* occurs through injection of tick saliva during feeding. In the United States, LD is endemic in the northeastern and mid-Atlantic regions, as well as in the north-central states (1) (Fig. 185.1). Most human infections with *B. burgdorferi* occur during the months of May through August, when both human outdoor activity and *Ixodes* nymphal activity are at their peaks. Humans primarily acquire *B. burgdorferi* from infected nymphs which, because of their small size, generally go unnoticed. Ticks must usually be attached for at least 36 hours for the transmission of the spirochete to occur, during which time engorgement of the tick is discernible (Fig. 185.2). Early diagnosis and prompt treatment are imperative in preventing morbidity related to the later stages of LD (2).

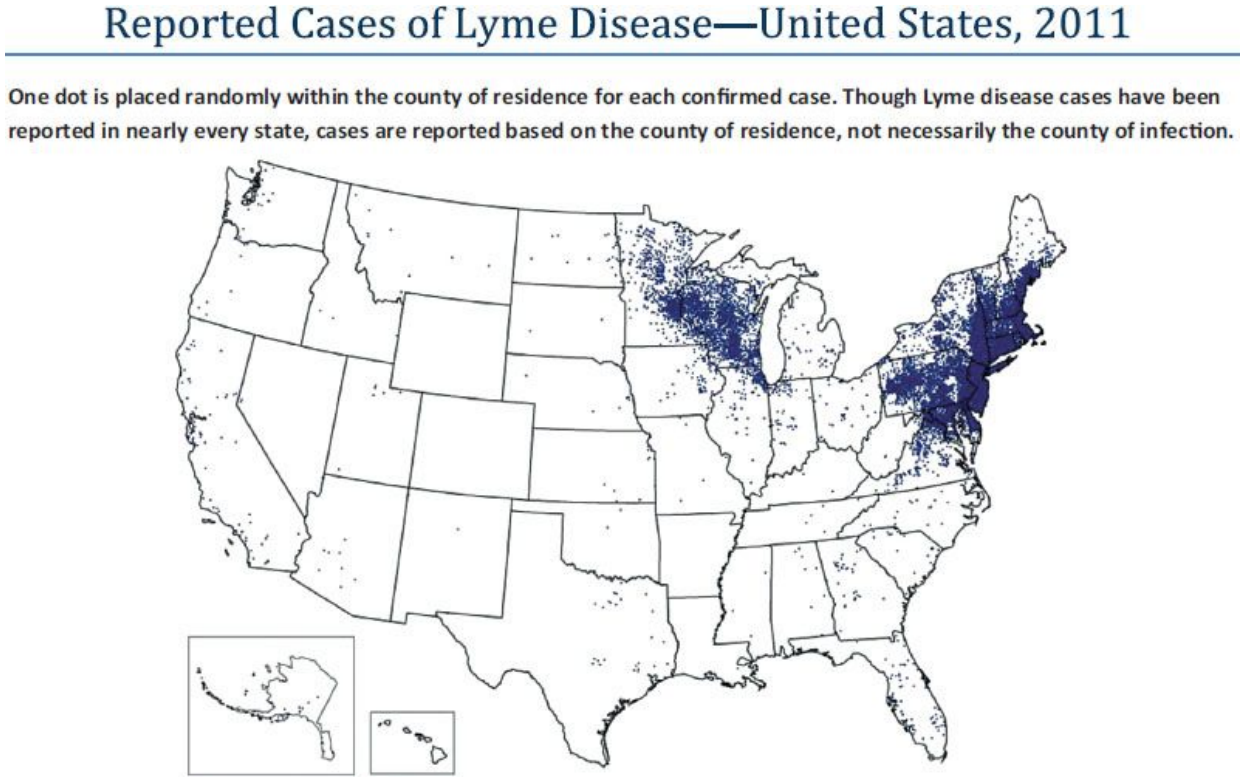

FIGURE 185.1 Reports of cases of Lyme disease to the Centers for Disease Control and Prevention (CDC), United States, 2011 (National Center for Emerging and Zoonotic Infectious Diseases, Division of Vector Borne Diseases, Bacterial Diseases Branch, Centers for Disease Control and Prevention, United States.) One dot is placed randomly within county of residence for each confirmed case. Although Lyme disease cases have been reported in nearly every state, cases are reported from the infected person's county of residence, not the place where they were infected. (Courtesy of Centers for Disease Control and Prevention.)

CLINICAL PRESENTATION

LD is comprised of a broad spectrum of clinical manifestations. The multisystem disorder presents in three clinical stages: (i) early localized infection, (ii) early disseminated infection, and (iii) late disseminated infection (Table 185.1). These stages may overlap, and certain clinical features may appear in isolation or recur at any time. To further complicate the clinical picture, later stages of the disease may present without any preceding signs or symptoms.

TABLE 185.1
Clinical Stages of Lyme Disease

Stage	Time	Manifestations
Early localized infection	7–14 d (range, 3–30 d)	Erythema migrans (EM) with or without nonspecific constitutional symptoms (fever, malaise, fatigue, headache, myalgia, and arthralgia)
		Asymptomatic
Early disseminated infection	Days to weeks	Multiple or secondary EM lesions
		Nervous system
		Musculoskeletal system
		Heart
Late disseminated disease	Weeks to months	Arthritis
		Chronic neurologic manifestations

As with other spirochetal diseases, the portal of entry for LD is the skin or mucous membrane. Similarly, this is followed by widespread dissemination, a subsequent period of latency, and eventual multisystem involvement. LD typically begins with the hallmark cutaneous lesion, *erythema migrans* (EM). This rash is often accompanied by nonspecific constitutional symptoms. In the days to weeks following inoculation, and as the spirochete spreads throughout the body, neurologic and cardiac manifestations may begin to appear. Within months, arthralgias and other neurologic symptoms may also begin to occur (3).

Early Localized Infection

LD symptoms typically begin about 1 to 2 weeks after a tick bite, but can range anywhere from 3 to 32 days (4). EM is the most common clinical characteristic of early LD and is thought to occur in almost 90% of cases (5). The rash often radiates from the actual site of the tick bite but may also begin at a distant location. EM lesions classically appear as a red expanding rash, and vary in appearance (Fig. 185.3). Lesions are usually annular and often have a characteristically target-like appearance, with centrifugal clearing. The average diameter of an EM lesion is 5 to 6 in, but may range anywhere from 2 in to 2 ft (6). Most rashes expand gradually over time but rapid expansion is known to occur. The rash itself may or may not be warm to touch and is generally not painful or pruritic.

Lesions are usually smooth and rarely have some element of central induration, crusting, or necrosis (7). Common locations for tick attachment, and subsequent rash, include the axilla, groin, popliteal fossa, and base of the neck. With antibiotic therapy, the EM rash resolves within several days. Without treatment, primary and secondary lesions may persist for almost 4 weeks and with the likelihood of recurrent lesions.

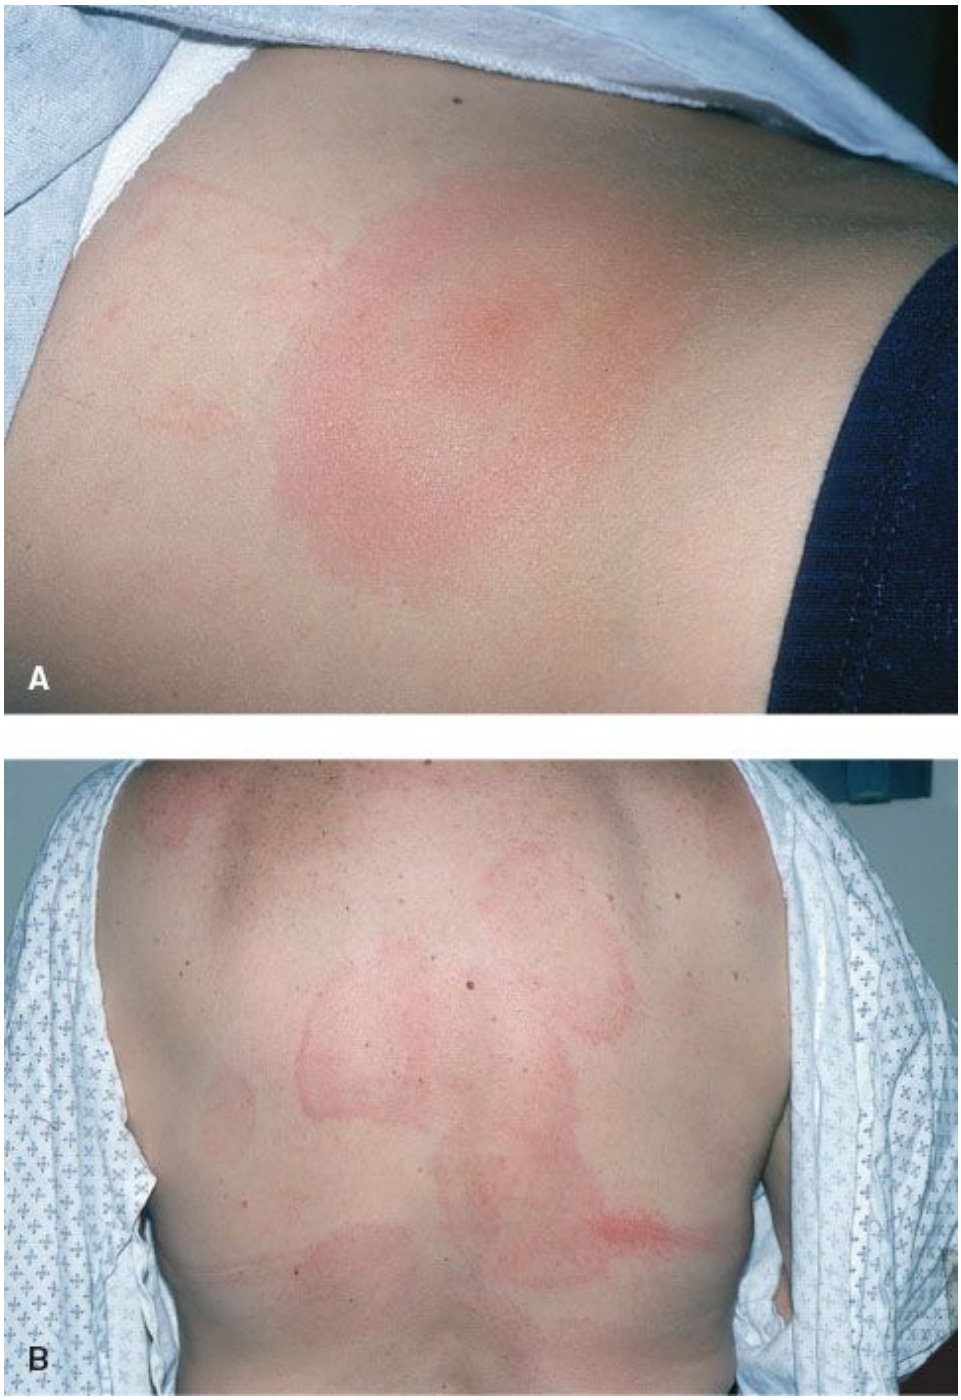

FIGURE 185.3 Erythema migrans rash of Lyme disease. **A:** Erythema migrans lesion on the torso. Note the target-like concentric rings with no scale. **B:** Erythema migrans lesions on the back. The rash may expand rapidly and cover a large area. (From Goodheart HP. *Goodheart's Photoguide of Common Skin Disorders,* 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003.)

Early constitutional symptoms in LD vary widely and often resemble a viral syndrome (8). Generalized fatigue and malaise affect the majority of patients. Other common symptoms include headache, low-grade fever, and anorexia. Headache may be accompanied by photophobia, nausea, and stiff neck, but neurologic and cerebral spinal fluid findings at this time are normal. Regional lymphadenopathy near the site of the tick bite often occurs. Musculoskeletal symptoms include arthralgias and myalgias and are frequently migratory and asymmetric. Upper respiratory and gastrointestinal signs and symptoms are uncommon in LD and their presence should suggest an alternate diagnosis (9). Given the nonspecific nature of these signs and symptoms, early LD can be easily misdiagnosed in the absence of the characteristic rash or history of a tick bite.

Early Disseminated Infection

Early disseminated disease occurs after a variable latent period, typically weeks to months after infection. It primarily involves the skin, nervous system, heart, and eyes. Patients may not have had any symptoms of early localized LD prior to the onset of disseminated signs and symptoms. The secondary cutaneous lesions of EM are characterized by multiple, smaller annular lesions (8). These typically spare the palms, soles, and mucosa. Neurologic and/or cardiac manifestations may occur without the presence of cutaneous involvement.

If LD is left untreated, nervous system involvement may affect up to 15% of patients. Neurologic manifestations include lymphocytic meningitis, cranial nerve palsies, peripheral neuropathies, and radiculoneuropathies (10). Lyme meningitis is usually associated with headache, nausea, lethargy, and irritability. Computed tomography will be normal in these patients, and upon cerebrospinal fluid (CSF) analysis, a distinguishing feature of Lyme meningitis is a predominant lymphocytic pleocytosis. Cranial nerve palsies may be unilateral or bilateral, with LD being one of the few causes of bilateral cranial nerve palsies. The facial nerve is the most commonly

affected cranial nerve. Peripheral neuropathies may include motor or sensory radiculopathies as well as mononeuritis.

Lyme carditis occurs in 4% to 10% of untreated LD patients and is usually transient (11). The average time of onset is approximately 5 weeks after the initial infection. Lyme bacterium can infect all aspects of the heart, including the conduction system, inner and outer membranes, muscle, and rarely, the valves. Symptoms of Lyme carditis are nonspecific and include light-headedness, syncope, shortness of breath, palpitations, and chest pain. Cardiac contractility may be transiently decreased due myopericarditis. The most common clinical feature is atrioventricular conduction block cause by impaired electrical signaling, occurring in almost 90% of patients (12). Heart block is often high grade or complete and usually resolves within 6 weeks. Heart block is rarely complete and permanent, requiring insertion of a pacemaker.

Ocular manifestations of LD include conjunctivitis, keratitis, choroiditis, retinal detachment, optic neuritis, and blindness. Papilledema is associated with Lyme encephalitis.

Late Disseminated Infection

Late LD usually occurs months to years after the initial infection. The chronic phase is typically associated with arthritis and less commonly, neurologic symptoms. The arthritic manifestations may be intermittent or persistent, and characteristically involve large joints, especially the knee. Joint effusions may be present but are relatively asymptomatic. Other joints less commonly affected include the shoulder, elbow, hip, and ankle. Prior to antibiotic therapy, almost half of all untreated patients developed attacks of joint swelling and pain. These episodes are usually brief, lasting weeks to months, with variable periods of exacerbations and remissions in between (8). In general, episodes become less frequent and less severe over time. Up to 10% of untreated patients develop chronic synovitis.

Neurologic manifestations of chronic disease vary widely and are often difficult to differentiate from other diseases, especially in the absence of any antecedent symptoms. Severe fatigue is commonly

reported in late disease. LD encephalopathy may manifest as subtle disturbances in cognition, mood, memory, or sleep. Central and peripheral nerve involvement is also a typical feature of late LD. As with early disease, it can involve the cranial nerves, spinal roots, and peripheral plexuses. Patients may experience radicular pain or numbness, including tingling in the hands and feet.

Acrodermatitis chronica atrophicans is a late cutaneous finding seen primarily in Europe. It typically occurs on the extensor surfaces of the body and is more common in older women. Lesions are initially characterized by a slight bluish-red discoloration with edematous infiltration. Over time, the rash may enlarge and eventually atrophies, resembling localized scleroderma (13).

DIFFERENTIAL DIAGNOSIS

Given the wide variety of clinical manifestations of LD, there is an extensive list of differential diagnoses. It is useful to consider common presentations of LD by stage and by system, and by the clinical features that help distinguish them.

In early LD, the range of constitutional symptoms may appear as “flu-like” symptoms. Diarrhea is not a feature of LD and if present, should help distinguish between LD and an enteroviral illness. Fatigue, sore throat, and adenopathy may suggest mononucleosis. Abdominal pain, nausea, and anorexia may be confused with appendicitis or hepatitis. The presence of arthralgias and myalgias may appear consistent with a connective tissue disease or other immune-mediated arthropathy. However, the musculoskeletal pain of LD is typically migratory, monoarticular, and occurs in brief attacks. Chronic fatigue syndrome and fibromyalgia are frequently misdiagnosed as LD (14).

The characteristic skin lesion of LD may be mistaken for the target lesions of erythema multiforme. However, EM does not involve the mucus membranes or palms and soles, as does erythema multiforme. In addition, the lesions of erythema multiforme are usually smaller and do not expand. EM may also be mistaken for erythema nodosum. The lesions of erythema nodosum are typically indurated and painful, whereas EM is not. EM may also appear similar to erythema

marginatum of rheumatic fever, but EM lesions are generally smaller, fewer, and slower in their migration. Other mimickers include hypersensitivity reactions and insect bites, but these typically appear hours, not days, after exposure. Given the gradually expanding area of erythema, EM may also be mistaken for bacterial cellulitis. However, the significant pain and possible toxicity associated with cellulitis is usually sufficient to make the distinction.

The cardiac sequelae of LD may suggest viral myocarditis, acute rheumatic fever (ARF), or acute coronary syndrome. In distinguishing Lyme carditis from ARF, EM usually precedes the cardiac manifestations in LD. In contrast, the cutaneous lesions of ARF typically coincide with the onset of arthralagias. Also, in ARF, there is usually evidence of a preceding streptococcal infection (in the form of an elevated antistreptolysin-O titer.) Valvular involvement is generally not a feature of Lyme carditis as it is in ARF.

The neurologic manifestations of LD give rise to a vast differential including viral or aseptic meningitis, encephalitis, multiple sclerosis, Bell palsy, dementia, and primary psychosis. In Lyme encephalopathy, CSF analysis usually reveals lymphocytosis, elevated protein and the presence of antibodies to *B. burgdorferi*.

The arthropathy of LD may be confused with that of autoimmune musculoskeletal disease, including rheumatoid, psoriatic, and reactive arthritis. Plain radiographs in these conditions may reveal an erosive process that is rare in LD (15). Numerous and symmetric joint involvement would also favor the diagnosis of rheumatoid or psoriatic arthritis over LD. Patients with Lyme arthritis do not have the typical morning stiffness or subcutaneous nodules seen in rheumatoid arthritis and often lack a positive rheumatoid factor.

ED EVALUATION

Prior to the recent advancement of reliable laboratory testing, the diagnosis of LD was essentially clinical (16). The presence of EM, in the context of recent exposure in an endemic area, is still virtually pathognomonic for LD. However, other nonspecific features occurring throughout the early and late stages of LD may make the

diagnosis difficult. Further diagnostic testing may be warranted under such circumstances to assist with the diagnosis of LD.

The initial evaluation of patients with suspected LD should include a detailed travel and exposure history, as well as a thorough skin examination. When the characteristic EM lesion is present in patients who reside or recently traveled to an endemic area, the diagnosis of LD can be made on clinical basis alone. Further testing is neither required nor recommended (17). In patients presenting with signs and/or symptoms of early disseminated or late LD, further serologic testing may be useful. Routine laboratory studies are not clinically useful at any stage of the disease.

Serologic testing should be considered an adjunct to the clinical diagnosis of LD, as it does not exclusively establish nor exclude the diagnosis. The Infectious Diseases Society of America (IDSA) has instituted guidelines for the indications for serologic testing (7). According to the IDSA, serologic testing should be performed in patients who meet **all** of the following criteria:

1. A recent history of having resided in or traveled to a LD endemic area **and**
2. A risk factor for tick exposure **and**
3. Symptoms consistent with early disseminated or late LD

Serologic testing should not be performed in patients with EM, for screening of asymptomatic patients living in endemic areas, or for patients with nonspecific symptoms alone.

Two-tier serologic testing is recommended to support the diagnosis of LD. The most commonly used initial test is enzyme-linked immunosorbent assay (ELISA). ELISA tests can detect both early (IgM) and late (IgG) immunoglobin antibodies. IgM antibodies typically appear 3 to 6 weeks after infection and as such, assays may be negative during the first several weeks. Furthermore, IgM returns to nondiagnostic levels 4 to 6 weeks after their peak. IgG antibodies may be detectable 2 months after initial exposure and typically peak at 12 months. If the ELISA test is positive or equivocal for IgM or IgG, then a Western blot should be performed. If the ELISA is negative, no further testing is recommended (18). False-positive ELISA testing for LD occurs in at least 5% of the general population

and is commonly attributed to other spirochetal diseases (most notably, *Treponema pallidum*), bacterial infections, viral illnesses, and autoimmune disorders. Seropositivity by two-tier testing simply indicates the presence of antibodies to the bacteria causing LD. It alone does not confirm the diagnosis of active LD. In addition, antibodies may be present for years after LD treatment and cure.

Other tests including immunofluorescent staining, lymphocyte transformation tests, and polymerase chain reaction (PCR) should be used with caution, as their accuracy has yet to be established (17). In cases of suspected neurologic involvement, routine CSF analysis should be performed for the evaluation of meningitis. CSF PCR used to detect the presence of *B. burgdorferi* DNA is limited by low sensitivity. Therefore, a negative PCR does not exclude LD. PCR of the urine is of no proven value and should not be used.

KEY TESTING

- No testing is necessary in patients with the characteristic skin lesion and a history of tick bite or those with a rash consistent with EM who live in endemic areas.
- Order serologic testing (ELISA) in selected patients to confirm exposure. Note, however, that false-positive ELISA testing occurs in approximately 5% of the population.
- Do not perform serologic testing for screening in asymptomatic patients or for patients with nonspecific symptoms only.

ED MANAGEMENT

The emergent management of patients with suspected LD should focus on recognizing the many forms of the illness, obtaining appropriate diagnostic studies, and initiating therapy as necessary. Most, if not all, other management may be performed in the appropriate outpatient setting.

Active *B. burgdorferi* infection is usually amenable to antibiotic therapy, and treatment can be started in the emergency department (ED). The decision as to whom to treat can be difficult. This assessment should be based on a combination of clinical presentation

and when appropriate, serologic testing. Fortunately, most decisions regarding antibiotic therapy are essentially nonurgent and can be made in consultation with the patient's primary physician. Treatment is undoubtedly indicated for the patient with the characteristic skin lesion and history of a tick bite in an endemic area. Prompt treatment of early disease shortens the duration of symptoms and usually prevents progression to later stages.

Treatment regimens for LD vary by disease stage and clinical manifestation. Table 185.2 is a summary of recommended antibiotic regimens. Oral therapy with doxycycline or amoxicillin is recommended for treatment of early localized or early disseminated LD. Amoxicillin is preferred for pregnant or lactating women and for children younger than 8 years old (7). Macrolide antibiotics should be reserved for patients who are unable to take doxycycline, amoxicillin, or cefuroxime, and should otherwise not be used as first-line treatment. The overall duration of antibiotic therapy should be tailored to the severity of illness and clinical response time. It should be noted that Jarisch–Herxheimer-like reactions (fever, chills, myalgias, headache, tachycardia, and tachypnea) may occur in the first 24 hours of treatment.

TABLE 185.2
Recommended Antibiotic Regimens

	Drug	Adult Dosage	Pediatric Dosage[a]
Early Lyme Disease			
Alternative	Doxycycline[b]	100 mg PO bid for 14–21 d	Age <8 yrs: Not recommended Age ≥8 yrs: 1–2 mg/kg bid (maximum 100 mg/dose)
	or		
	Amoxicillin	500 mg PO tid for 14–21 d	50 mg/kg/d divided tid (maximum 500 mg/dose)
	Cefuroxime axetil	500 mg PO bid for 14–21 d	30 mg/kg/d divided two doses (maximum 500 mg/dose)
	or		
	Macrolides *(less effective than doxycycline or amoxicillin and not recommended as first-line therapy)*		
	Azithromycin	500 mg PO daily for 7–10 d	10 mg/kg/d (maximum 500 mg/d)
	Erythromycin	500 mg PO qid for 14–21 d	7.5 mg/kg bid (maximum 500 mg/dose
	Clarithromycin	500 mg PO bid for 14–21 d	12.5 mg/kg qid (maximum 500 mg/dose)
Neurologic Disease			
Facial nerve paralysis	As an isolated finding, oral regimens for early disease, used for at least 30 d, may suffice. As a finding associated with other neurologic manifestations, intravenous therapy is recommended.		
Lyme Meningitis[c]	Ceftriaxone	2 g IV daily for 14–28 d	75–100 mg/kg/d IV
Alternative	Doxycycline	200–400 mg/d in two divided doses orally for 10–28 d	
	Penicillin G	18–24 million units IV/d, divided into doses given q4h	200,000–400,000 units/kg/d, divided into doses given q4h
	Cefotaxime	2 g IV tid	150–200 mg/kg/d IV, divided into 3 or 4 doses
Cardiac Disease			
Mild[d]	Doxycycline[b]	100 mg PO bid × 21 d	
	or		
	Amoxicillin	250–500 mg PO tid × 21 d	50 mg/kg/d divided tid
More severe	Ceftriaxone	2 g IV daily by single dose for 14–21 d	75–100 mg/kg/d IV
	or		
	Penicillin G	18–24 million units daily in divided doses for 14–21 d	200,000–400,000 units/kg/d, divided into doses given q4h
Arthritis			
Oral	Doxycycline[b]	100 mg PO bid for 28 d	
	or		
	Amoxicillin	500 mg PO tid for 28 d	50 mg/kg/d divided tid
Parenteral	Ceftriaxone	2 g IV by single dose for 14–28 d	75–100 mg/kg/d IV
	or		
	Penicillin G	20 million units IV daily in divided doses for 14–28 d	300,000 units/kg/d IV

[a]Pediatric dosage should not exceed adult dosage.
[b]Tetracycline, 250–500 mg PO qid, may be substituted for doxycycline. Neither doxycycline nor any other tetracycline should be used for children younger than 8 years old or for pregnant or lactating women.
[c]Regimens for radiculoneuropathy, peripheral neuropathy, and encephalitis are the same as those for meningitis.
[d]Oral regimens are reserved for mild cardiac involvement (see text).
Adapted from Wormser GP, Dattwyler RJ, Shapiro ED, et al. The clinical assessment, treatment, and prevention of Lyme disease, human granulocytic anaplasmosis, and babesiosis: clinical practice guidelines by the Infectious Diseases Society of America. *Clin Infect Dis.* 2006;43(9):1089–1134.

Neurologic Disease

The management of patients with facial nerve palsies attributed to *B. burgdorferi* remains somewhat controversial. Lumbar puncture is not required in all patients, but is recommended in patients with a high clinical suspicion of CNS involvement. Patients with normal CSF may be treated with the same oral regimens used for patients with EM. In patients with evidence of CNS involvement, or other more serious complications (i.e., meningitis, encephalitis, cognitive deficits, or

other cranial neuropathies) treatment with parenteral antibiotic therapy is indicated (Table 185.2).

Cardiac Disease

Antibiotic treatment recommendations for patients with cardiac involvement vary by severity of heart block present (see Table 185.2). Patients with first-degree atrioventricular block or a PR interval <0.30 seconds may be treated orally, whereas those with high-degree atrioventricular block often require parenteral antibiotics. Temporary cardiac pacing may be necessary in severe cases. In most cases, heart block resolves completely with antibiotic therapy.

Arthritis

The diagnosis of Lyme arthritis should be confirmed by serologic testing of synovial fluid whenever possible. Treatment with a month long course of oral doxycycline or amoxicillin is usually effective, but response may be delayed for several weeks to months (see Table 185.2). Anti-inflammatory agents may be helpful in alleviating discomfort caused by an immune-mediated response.

Prophylaxis

Several recent studies have investigated the efficacy of prophylactic antibiotic therapy following a tick bite to prevent LD (19,20). There exists concern that treating only individuals who exhibit signs of illness will render some untreated for subclinical disease. Conversely, treatment may be unwarranted, ineffective and unnecessarily expose patients to medication side effects. A single dose of doxycycline has been shown to be effective in a subset of patients. The IDSA has established specific guidelines for the recommendation of antibiotic prophylaxis for the prevention of LD (Table 185.3) (7). According to these guidelines, patients must meet all of the following criteria: (a) The attached tick is identified as an adult or nymphal *Ixodes scapularis* tick (b) the tick is estimated to have been attached for ≤ 36 hours (by degree of engorgement or time of exposure) (c)

prophylaxis is begun within 72 hours of tick removal (d) the local rate of infection of ticks with *B. burgdorferi* is ≤20% and (e) doxycycline is not contraindicated (i.e., the patient is not <8 years of age, pregnant, or lactating). In patients meeting all of these criteria, the recommended dose of oral doxycycline is 200 mg for adults and 4 mg/kg, up to a maximum of 200 mg, in children ≤8 years of age. (Of note, this regimen has never been tested in children.) As the majority of patients infected with *B. burgdorferi* develop EM, and the typically excellent outcomes with early therapy, an alternative for these patients may be observation of the tick bite site and subsequent treatment if an EM rash develops.

TABLE 185.3
Guidelines for Prophylactic Treatment of Tick Bites

Attached tick is identified as an adult or nymphal *I. scapularis* tick and is estimated to have been attached for ≥36 hrs by degree of engorgement or time of exposure
Prophylaxis is initiated within 72 hrs of tick removal
Local rate of infection of ticks with *B. burgdorferi* is ≥20%
Doxycycline is not contraindicated in the patient being treated

Adapted from Wormser GP, Dattwyler RJ, Shapiro ED, et al. The clinical assessment, treatment, and prevention of Lyme disease, human granulocytic anaplasmosis, and babesiosis: Clinical practice guidelines by the Infectious Diseases Society of America. *Clin Infect Dis.* 2006;43(9):1089–1134.

CRITICAL INTERVENTIONS

- Initiate treatment for patients with a characteristic skin lesion and a history of tick bite or those with an EM rash who live in endemic areas.
- Order the ELISA test to confirm exposure but do not wait for positive assay before beginning therapy.
- Base treatment recommendations on the disease stage and clinical manifestations.

DISPOSITION

The decision regarding disposition of a patient with suspected LD is based on the stage of the disease and the severity of clinical symptoms. Nearly all patients with early LD can be discharged from the ED and appropriately managed as outpatients. Follow-up care should be arranged with a primary care physician, rheumatologist, or infectious disease specialist. Patients with more serious manifestations, including Lyme carditis with high-degree atrioventricular block or with significant neurologic involvement, often require hospital admission for monitoring, supportive care, and intravenous antibiotic therapy.

Common Pitfalls

- Symptoms of late LD may occur without any preceding early symptoms. The initial tick bite may have gone unnoticed or the transient appearance of a rash forgotten, and as such, LD may not be considered in the differential diagnosis.
- Many disorders share nonspecific symptoms often seen with Lyme borreliosis and are commonly misdiagnosed as LD. This frequently results in inappropriate treatment with antibiotics.
- If an attached tick is removed quickly, no other treatment is usually necessary. However, if the tick is engorged, LD prophylaxis may be considered.
- Serologic testing should only be performed in a selected subset of patients. Indiscriminate testing of patients results in a high rate of false-positive tests.

CHAPTER 186

Rocky Mountain Spotted Fever

Paul I. Musey Jr and Michael A. Gibbs

Rocky Mountain spotted fever (RMSF) is the most common tick-borne illness in the United States and one of the most serious systemic infections seen in clinical practice. Emergency physicians must maintain a high index of suspicion for RMSF and consider early empiric therapy in the patient at risk. In 2010 epidemiologists changed the name of RMSF to Spotted Fever Rickettsiosis to reflect crossreactivity between spotted fever rickettsial pathogens. We will, however, continue to refer to RMSF for the purpose of this chapter.

Education, awareness, and a high index of suspicion have helped to decrease the case fatality rate of RMSF, which had been hovering between 5% and 10%, down to around 0.5% (1). However, the disease continues to confound physicians because of its sporadic occurrence and nonspecific clinical presentation. Difficulties in making the diagnosis are especially relevant because the prognosis is directly related to the timeliness of appropriate treatment. The greatest challenge to physicians is diagnosing RMSF early in its clinical course, when antibiotic therapy is most effective.

In one study, 90% of patients were seen by a physician within 5 days of the onset of symptoms, yet less than half received treatment before day 6. Patients who received antirickettsial therapy within 5 days were significantly less likely to die than were those who received treatment later (6.5% vs. 22.9%). Three independent predictors of a failure to initiate therapy on first presentation to a

physician were absence of a rash, presentation between August 1 and April 30, and presentation within the first 3 days of illness.

In 2004, the Centers for Disease Control (CDC)'s Viral and Rickettsial Zoonoses Branch developed guidelines for the diagnosis and management of RMSF and the other major tick-borne illnesses. This report emphasized that health professionals must (a) recognize epidemiologic features and clinical manifestations of the disease, (b) develop a differential diagnosis that includes tick-borne illness, (c) understand that doxycycline is the treatment of choice for both adults and children, (d) understand that early empiric antibiotic therapy can prevent serious morbidity and mortality, and (e) report suspected and confirmed cases of RMSF to local public health authorities (2). Emergency physicians on the front line will be expected to play a significant role in achieving these outcomes.

Epidemiology

RMSF is caused by *Rickettsia rickettsii,* an obligate intracellular bacterium. It is transmitted by several species of ticks that also serve as the reservoir or natural host. In the eastern states, the American dog tick, *Dermacentor variabilis,* is the major vector; the Rocky Mountain wood tick, *Dermacentor andersoni,* is the predominant vector in western states. More than 95% of cases occur between April 1 and September 1, corresponding to the seasonal life cycle of the tick.

RMSF is prevalent throughout the continental United States, with cases reported from each of the contiguous 48 states except Vermont and Maine. Although first described in Idaho and Montana, RMSF is now infrequent in the western states. There has been a coincident steady increase in the number of cases in the southeastern United States. Between 2003 and 2010, more than half (>60% in 2010) of the reported cases of RMSF came from only five states: North Carolina, South Carolina, Tennessee, Oklahoma, and Arkansas (1,3).

Although previous studies have indicated that the highest incidence of RMSF is in children less than 10 years of age, CDC surveillance data between 2003 and 2010 demonstrate the highest

age-specific incidence among persons aged 40 to 64 years (1–3). The case fatality rate is highest in those aged 40 or older (8.2%, compared to 2.3% for those younger than 40). The case fatality rate is also higher for individuals whose treatment is begun more than 3 days after the onset of symptoms (6.2%, compared with 1.3% for those treated within the first 3 days). RMSF is more common in men than in women, reflecting a greater potential exposure to the tick vector. Despite the fact that RMSF is more common in whites than in African Americans, the case fatality rate is significantly higher in the latter group (16% vs. 3%), a fact most likely related to the difficulty of detecting the characteristic rash on dark skin.

CLINICAL PRESENTATION

RMSF is a systemic vasculitis that may affect any organ system. For this reason, signs and symptoms are varied and often nonspecific. The majority of patients first seek medical attention during the first 2 to 4 days of illness, after an incubation period of approximately 5 to 10 days. A history of a tick bite or the presence of a tick is elicited in just more than half of patients. The onset of illness is usually acute, with fever, chills, headache, and myalgias. Headache tends to be the predominant complaint in adults and can be severe. Nausea, vomiting, abdominal pain, and anorexia are also common early in the course of illness. The clinical findings and their prevalence are summarized in Table 186.1.

TABLE 186.1
Clinical Manifestations of Rocky Mountain Spotted Fever

Signs or Symptoms	Any Time (%)	First 3 Days (%)
Fever (100–102°F)	99	73
Fever (>102°F)	90	63
Fever + rash + tick bite	67	3
Dermatologic		
Any rash	88	49
Rash, maculopapular	82	46
Rash, petechial, or hemorrhagic	49	13
Rash on palms and soles	74	28
Edema	18	3
Conjunctivitis	30	13
Neurologic		
Headache, mild/moderate	91	71
Headache, severe	57	40
Altered mental status	26	6
Meningeal irritation	18	5
Decreased hearing	7	1
Seizures	8	2
Cardiopulmonary		
Pneumonitis	12	2
Dysrhythmias	7	1

Myalgias, mild/moderate	83	57
Myalgias, severe	47	25

From Helmick CG, Bernard KW, D'Angelo LJ. Rocky Mountain spotted fever: Clinical, laboratory, and epidemiological features of 262 cases. *J Infect Dis*. 1984;150:480–488.

A *rash* of one type or another is seen in the majority of patients with RMSF, but "Rocky Mountain spotless fever" has been reported in 5% to 15% of cases (4). The rash may be absent at the onset of symptoms and may not be appreciated in patients with dark skin. The rash usually appears on the third day of illness and is first seen

on the palms, soles, wrists, and ankles and progresses centripetally, but the rash may begin on the trunk (approximately 10%) or have a diffuse onset (approximately 10%). Lesions are initially macular and later evolve to become petechial and maculopapular in 50% of cases. See Figures 186.1 and 186.2. Application of a tourniquet or blood pressure cuff may cause the appearance of additional lesions distally (Rumpel–Leede sign). In severe cases, there may be extensive purpura, skin sloughing, ulceration, and gangrene. Rarely, an eschar may be seen at the site of the tick bite (5).

FIGURE 186.1 RMSF: Petechial rash on forearm. (Courtesy of Steven Manders, MD.)

FIGURE 186.2 RMSF: Maculopapular rash on palms, wrists, and forearms. (Courtesy of Sidney Sussman, MD.)

The *central nervous system* is perhaps the most crucial target "organ" of RMSF. Varying degrees of meningeal inflammation and cerebral vasculitis cause a wide range of neurologic signs and symptoms. Rickettsial encephalitis (severe headache, confusion, stupor, coma, and seizures) carries a particularly grave prognosis (6). Focal neurologic deficits, deafness, sensory neuropathy, tardive dyskinesia, and Guillain–Barré syndrome have all been described in patients with RMSF (5,7).

Neuroimaging with computed tomography (CT) or magnetic resonance imaging (MRI) may reveal a variety of subtle nonspecific abnormalities including infarcts, cerebral edema, meningeal

enhancement, and increased signal of the perivascular spaces. There is some evidence that the presence of these radiographic findings may be associated with a less favorable outcome (8). In patients with central nervous system involvement, the cerebrospinal fluid is almost always abnormal.

The *cardiovascular* effects of RMSF are the result of myocarditis and myocardial vasculitis (9). Clinical manifestations include varying degrees of atrioventricular (AV) block, dysrhythmias (atrial and ventricular tachycardia, atrial fibrillation), and left ventricular dysfunction. It has been hypothesized that cardiac involvement may play an important role in the cases of fatal RMSF.

Rickettsial *pneumonitis* results from microvascular injury and leakage of fluid into the interstitial tissues and alveolar airspaces. This potentially life-threatening complication occurs in 2% to 17% of patients. Signs and symptoms include cough, dyspnea, pleuritic chest pain, and hypoxemia. Chest radiography typically reveals diffuse patchy infiltrates (10).

Up to 80% of patients with RMSF have prominent *gastrointestinal* complaints early in the course of disease, including abdominal pain, nausea, vomiting, and diarrhea. This symptom complex may lead the clinician to incorrectly diagnose acute gastroenteritis or even an acute surgical abdomen. Not surprisingly, patients with RMSF have undergone exploratory laparotomy for suspected appendicitis, cholecystitis, and perforated diverticulitis.

DIFFERENTIAL DIAGNOSIS

When patients present early, the accurate diagnosis of RMSF depends on clinical suspicion and an understanding of local epidemiology. It would not be difficult to imagine attributing fever, malaise, headache, and myalgias in a well-appearing patient to a nonspecific viral syndrome. As the disease progresses, the individual patient with RMSF may be misdiagnosed as having a number of specific viral illnesses (e.g., measles, infectious mononucleosis), meningococcemia, gastroenteritis, acute surgical abdomen, pneumonia, toxic shock syndrome, ehrlichiosis, or encephalitis.

RMSF may also mimic noninfectious entities including idiopathic thrombocytopenic purpura, thrombotic thrombocytopenic purpura, drug reaction, and immune-complex vasculitis.

As with RMSF, diagnosis of meningococcemia must be made quickly and accurately. Both diseases may present with headache, fever, nausea, vomiting, and upper respiratory symptoms. However, meningococcemia is typically more abrupt in onset and its rash (petechial without characteristic pattern) appears within 24 hours of symptom onset. Gram stain of cerebrospinal fluid is diagnostic, and the causative organism can also be detected using latex agglutination and counterimmunoelectrophoresis. If either diagnosis is in question, immediate therapy for both RMSF and meningococcemia is mandatory.

Distinguishing RMSF from an enteroviral infection can also be quite difficult. Fever, headache, aseptic meningitis, and a maculopapular rash are common to both presentations. The rash of enteroviral infections usually starts centrally but may also involve the palms and soles. Petechial lesions are not uncommon.

ED EVALUATION

As with most conditions in medicine, the evaluation of a patient suspected of having RMSF begins with a careful history and physical examination. Close attention should be paid to high-risk historical features (recent outdoor activities, i.e., camping, presentation between April and September, presentation in an endemic area, etc.). A viral syndrome with an associated rash should trigger RMSF to be on the differential and prompt further investigation.

Laboratory studies typically available in the emergency department (ED) offer little help in the diagnosis of RMSF. Although routine studies may provide subtle clues, these are inconsistent and nonspecific. *It must be emphasized that treatment must be based on clinical findings alone and should never be withheld while waiting for specific serologic confirmation of the disease.*

Hematologic findings seen in RMSF include a normal or decreased white blood cell count, anemia, thrombocytopenia, and a high

peripheral band count. Anemia and thrombocytopenia are seen in 30% and in 30% to 50% of patients, respectively (11). Hyponatremia is seen in roughly one-fourth of cases. Elevation of serum transaminases and bilirubin may be noted in patients with hepatic involvement (10).

A lumbar puncture is mandatory in all patients with significant headache and fever or signs of meningeal irritation. Elevated cerebrospinal fluid protein and pleocytosis are the typical findings in RMSF. Differential cell counts may reveal either lymphocytic or polymorphonuclear cell predominance. Of note, a cerebrospinal fluid white blood cell count >100 cells/μL is uncommon, occurring in only 11% of cases. Because the distinction between RMSF and meningococcemia can be difficult, a "positive tap" in a patient with high-risk signs and symptoms should prompt immediate therapy for both.

Serologic testing is of value in the retrospective confirmation of RMSF, but is not helpful in the acute setting. Immunofluorescence antibody (IFA) assay is considered the gold standard serologic assay for rickettsial diseases, but enzyme-linked immunosorbent assay (ELISA) is becoming more frequently used. Both tests rely on the presence of antibodies to *R. rickettsii* antigens in sera, and as such, sensitivity is dependent on the timing of collection of the sample. The IFA is estimated to be 94% to 100% sensitive after 14 days, and that sensitivity is increased if paired samples are tested (12). These serologic tests may not be routinely available in all hospital settings but can usually be obtained through state health department laboratories. Because the serologic diagnosis of RMSF can be complex, consultation with local and regional experts will help the emergency physician make the right choice when the diagnosis is in question.

Identification of *R. rickettsii* in skin biopsy specimens can be a helpful diagnostic test for RMSF in the acute setting. This technique can be used only when the rash is present. A punch biopsy should be obtained at the center of a well-defined lesion. Immunofluorescent staining of frozen section samples demonstrates the organism in about 70% of cases.

KEY TESTING

- There is no specific laboratory study to confirm RMSF in the ED. To avoid the increased morbidity and mortality associated with delays in therapy, treatment should be initiated on clinical grounds when the diagnosis is suspected.
- In patients with signs and symptoms of central nervous system involvement lumbar puncture should be performed to rule out alternative diagnoses (e.g., meningococcemia) as well as to aid in the diagnosis of RMSF.

ED MANAGEMENT

It is not only appropriate but essential for the clinician practicing in an endemic area to initiate antibiotic therapy in the patient with clinical findings suggestive of, but not necessarily diagnostic of, RMSF without the aid of serologic testing.

Doxycycline is considered the drug of choice for the treatment of RMSF in both adults and children. The recommended dose is 100 mg administered twice daily (orally or intravenously) for adults, or 2.2 mg/kg body weight per dose for children $<$45.4 kg (100 lb). Intravenous therapy is indicated for patients who are severely ill (not appropriate for outpatient management) or who are not able to tolerate oral medications (2).

The use of doxycycline to treat children with RMSF is no longer a subject of controversy. Historical concerns over dental staining were based on studies that involved children who had received prolonged courses of the drug. Limited use of doxycycline in young children does not result in significant discoloration of permanent teeth, and the clinician should never withhold appropriate therapy in this setting (13).

Chloramphenicol is the treatment of choice for RMSF during pregnancy. Tetracyclines are contraindicated in pregnancy because of the risk of malformation of teeth and bones in the fetus and hepatotoxicity and pancreatitis in the mother. The recommended dose is 50 to 100 mg/kg/d. Side effects associated with chloramphenicol include bone marrow depression, hemolytic

anemia in patients with the Mediterranean form of glucose 6-phosphate dehydrogenase deficiency, “gray baby” syndrome in premature infants and neonates, and (rarely) aplastic anemia. Because chloramphenicol is metabolized by the liver, drug interactions may occur in patients taking either inhibitors or inducers of hepatic enzymes (2).

Regardless of the agent selected, patients should be treated for at least 7 to 10 days, and therapy should be continued as necessary until the patient is afebrile and clinically improved for 24 to 48 hours (11).

Successful treatment of the critically ill patient with RMSF requires meticulous attention to fluid and electrolyte balance. Widespread systemic vasculitis and resultant fluid shifts may cause hypotension, oliguric renal failure, disseminated intravascular coagulation, adult respiratory distress syndrome, and shock. In the treatment of these complications, the clinician must maintain a delicate balance between adequate restoration of intravascular volume and overresuscitation with precipitation of pulmonary edema. Isotonic saline should be given in small serial boluses. Vasopressors may be required in patients with impaired tissue perfusion that is unresponsive to fluid therapy. Hemodynamic monitoring with a pulmonary artery catheter may provide the treating physician with an extra margin of safety and is recommended in the unstable patient.

Prevention

Emergency physicians play an important role in educating the public about disease prevention. People who reside or work in tick-infested areas should be informed about tick-borne diseases and their prevention. The optimal method for preventing RMSF is the avoidance of tick-infested areas. People entering these areas should wear protective clothing and use tick repellents. Exposed areas of the body should be examined for attached ticks. Ticks should be removed by grasping them with fine tweezers at the point of attachment and pulling slowly and steadily.

CRITICAL INTERVENTIONS

- Suspect RMSF in patients presenting with clinical manifestations and a history of possible tick exposure.
- Initiate antibiotic therapy in the patient with clinical findings suggestive of, but not necessarily diagnostic of, RMSF without the aid of serologic testing.

DISPOSITION

When an otherwise healthy, clinically stable patient presents with one or several clinical findings suggestive of RMSF, it is appropriate to initiate empiric therapy without confirmatory diagnostic testing and to discharge the patient with close follow-up. In endemic areas, patients presenting with a flu-like illness during the spring or summer months are frequently discharged home on doxycycline. In this situation, contact with a primary care provider or a return visit to the ED in 24 to 72 hours is a sensible part of the discharge plan.

Patients presenting with more severe disease should be admitted to the hospital. This group includes those with significantly abnormal vital signs, dehydration, or end-organ dysfunction (e.g., cerebritis, pneumonitis, myocarditis). Prompt administration of antibiotics and early consultation with an intensivist and an infectious disease specialist are also appropriate.

Common Pitfalls

- Failure to consider the diagnosis of RMSF in the patient with fever and a "viral syndrome" during the peak season (April 1 to September 1) in an endemic area
- Failure to recognize that roughly 15% patients with RMSF present without a rash ("Rocky Mountain spotless fever"). Among ultimately fatal cases, a rash is absent at the time of first presentation to a physician in more than 80%.
- Failure to appreciate the often prominent gastrointestinal features of RMSF, resulting in an incorrect diagnosis of gastroenteritis

- Failure to initiate appropriate antirickettsial therapy in a timely fashion
- Overreliance on laboratory testing, which offers little in the acute phase of RMSF, or withholding of indicated therapy while waiting for definitive serologic confirmation of the disease

CHAPTER 187
Other Tick-Borne Diseases

Ann P. Nguyen

The most prevalent North American tick-borne diseases are: Lyme disease, Rocky Mountain spotted fever, anaplasmosis, ehrlichiosis, tularemia, babesiosis, tick-borne relapsing fever, Colorado tick fever (CTF), and tick paralysis. These diseases peak in incidence from April to September when the feeding activity of ticks coincides most with the outdoor activity of humans (1,2). Lyme disease, Rocky Mountain spotted fever, and tick paralysis are discussed in other chapters. The remaining diseases are discussed here (Table 187.1).

TABLE 187.1
Common North American Tick-Borne Diseases

Disease	Causative Agent	Tick Vector	Geographic Distribution	Clinical Features	Treatment
• Human monocytic ehrlichiosis (HME)	*Ehrlichia chaffeensis* *Ehrlichia ewingii* (Rickettsia)	*Amblyomma* *Dermacentor* *Ixodes*	Southeast South central	• Nonspecific febrile syndrome	Doxycycline or rifampin
• Human ewingii ehrlichiosis (HEE)				• Rash in 10–40% • Elderly and immunosuppressed patients at risk	
• Human granulocytic anaplasmosis (HGA)	*Anaplasma phagocytophilum* (Rickettsia)	*Ixodes*	Northeast Midwest California	• ARDS, thrombocytopenia, DIC, opportunistic infections	Doxycycline or rifampin
• Tularemia	*Francisella tularensis* (Bacteria)	*Amblyomma*	Southeast South central	• Nonspecific febrile syndrome	Streptomycin or gentamicin
		Dermacentor	All regions	• Ulceroglandular, glandular, typhoidal, pneumonic, oropharyngeal, and oculoglandular forms	
• Babesiosis	*Babesia microti* (Protozoan)	*Ixodes*	Northeast	• Fever, sweats, hemolysis • Splenectomized and other immunosuppressed patients at risk	Quinine + clindamycin or Atovaquone + azithromycin
• Tick-borne relapsing fever	*Borrelia* species: *B. hermsii* *B. parkeri* *B. turicatae* *B. dugesi*	*Ornithodoros*	Rocky Mountains Texas, Mexico	• Multiple remissions and relapses • Neonates and pregnant women at risk • Jarisch–Herxheimer reaction when treated	Doxycycline or Tetracycline or Erythromycin
• Colorado tick fever (CTF)	CTF virus (*Coltivirus*)	*Dermacentor*	Rocky Mountains	• Biphasic fever pattern • Prolonged convalescence	Supportive

Ehrlichiosis and Anaplasmosis

Caused by gram-negative intracellular coccobacilli, ehrlichiosis and anaplasmosis are clinically similar, identically managed diseases. Human monocytic ehrlichiosis (HME) is caused by *Ehrlichia chaffeensis* and human ewingii ehrlichiosis (HEE) is caused by *Ehrlichia ewingii.* Lone Star ticks (*Amblyomma americanum*) are the main vector, although *Dermacentor* and *Ixodes* species have also been implicated (3,4). Human granulocytic anaplasmosis (HGA) is caused by *Anaplasma phagocytophilum.* HGA is transmitted by deer ticks (*Ixodes scapularis*) in the Eastern United States and by western blacklegged ticks (*Ixodes pacificus)* in the Western United States (2,5). Transmission via blood transfusion, blood exposure, and transplacental routes have also been documented (3,6).

HME and HEE occur in the Southeastern and South Central United States whereas HGA is distributed in the Northeastern and Midwestern states and California (3,4,5). Since 2000, the Centers for Disease Control (CDC) consider HME and HGA to be reportable diseases. From 2000 to 2010, up to 961 HME and 1,163 HGA cases per year have been identified (7,8). HEE was declared nationally reportable in 2008. This disease has been found only in immunosuppressed patients and is much more rare with 28 reported cases between 2008 and 2010 (7).

CLINICAL PRESENTATION

HME, HEE, and HGA present after a 5- to 14-day incubation period with fevers, headache, myalgias, nausea, vomiting, and occasionally diarrhea. Respiratory symptoms are rare. Up to 20% of ehrlichiosis patients show evidence of central nervous system infection such as meningitis, encephalitis, seizures and coma, whereas in anaplasmosis, peripheral nerve palsies predominate (1,3,4,5). A nonpruritic, erythematous maculopapular or petechial rash appears on the trunks and extremities of most ehrlichiosis patients and 10% of anaplasmosis patients after 5 to 7 days of illness (1,3,4,5). While typically displaying milder disease than adults, children more often experience rash, abdominal pain, and altered mental status (1,6).

Most patients recover spontaneously within 2 weeks, although up to one-third of anaplasmosis patients and half of ehrlichiosis patients require hospitalization (2,3,5). Poor outcome is linked to age over 60, HIV infection, immunodeficient states, diabetes mellitus, malignancy, connective tissue disease, and delayed administration of appropriate antibiotics (1,6,9). Complications occur in 10% to 20% of patients and include septic shock, acute respiratory distress syndrome (ARDS), thrombocytopenia with life-threatening hemorrhage, disseminated intravascular coagulation (DIC), acute renal failure, myocarditis, rhabdomyolysis, meningoencephalitis, and seizures. Even after appropriate antibiotics, ehrlichiosis carries a 1% to 3% mortality rate and anaplasmosis, 0.5% (3,7,8).

ED EVALUATION AND MANAGEMENT

Aside from the previously described rash, physical examination is generally unrevealing. Some patients have hepatomegaly or splenomegaly. Altered sensorium or meningismus suggest ehrlichiosis while peripheral neuropathies suggest anaplasmosis. Laboratory testing may show leukopenia, thrombocytopenia, anemia, hyponatremia, and mild-to-moderate elevation of aspartate amino transferase (AST) and alanine aminotransferase (ALT).

Polymerase chain reaction (PCR) is the test of choice in the ED (1,3). Diagnosis can also be made by visualizing intracellular bacteria on peripheral blood smear, but these are seen less than 20% of the time in ehrlichiosis and less than 80% of the time in anaplasmosis (2,3). Serologic testing is not helpful in the ED due to its insensitivity during the first 2 weeks of illness (3). Blood cultures may be sent, but are typically unsuccessful in isolating *Ehrlichia* or *Anaplasma* (4).

Test all patients with suspected HME, HEE, or HGA for Lyme disease, as these diseases share the same tick vectors. Coinfection with Lyme disease, which occurs 10% to 30% of the time, is associated with greater disease severity (3,4,5).

If any of the complications listed here occur, initiate resuscitative therapy. Most patients will not be critically ill and will need supportive care only. Initiate empiric antibiotics to high-risk patients,

as confirmatory tests may take days to complete and therapy delay is associated with poor outcome (1,6,9). The drug of choice is doxycycline, 100 mg PO or IV q12h (children: 2.2 mg/kg q12h) for 7 to 10 days (1,2,3,5). An alternative is tetracycline, 500 mg PO q6h (children: 6.25 to 12.5 mg/kg q6h) for 7 to 10 days. Use rifampin, 300 mg PO q12h (children: 10 mg/kg q12h) for 7 to 10 days, in patients allergic to tetracycline antibiotics (5). Pediatric age or pregnancy are no longer considered contraindications to doxycycline (1,3,4,5). If coinfection with Lyme disease is suspected, extend the antibiotic course for a full 14 to 21 days (2,5). Failure to improve after 24 to 48 hours of doxycycline or rifampin indicates a diagnosis other than HME, HEE, or HGA.

DISPOSITION

Admit all patients with complications and those belonging to high-risk groups for 24 to 48 hours of observation. Discharge nontoxic patients on oral antibiotics, with arrangements for re-evaluation in 48 hours and for follow-up of serologic testing.

Tularemia

Tularemia is caused by a gram-negative coccobacillus, *Francisella tularensis*. Half of all tularemic disease is transmitted by tick vectors: the Lone Star tick (*A. americanum*) in the southeastern and south central states, the Rocky Mountain wood tick (*Dermacentor andersoni*) in the western states, and the dog tick (*Dermacentor variabilis*) throughout North America (1). Arkansas, Massachusetts, Missouri, Oklahoma, and South Dakota accounted for 50% of tick-borne tularemia from 2001 to 2010 (10). The remainder of cases are transmitted by insect vectors, handling infected animals (primarily rabbits and rodents), ingesting contaminated meat or water, inhaling aerosolized bacteria, or autoinoculating mucous membranes (1).

From 2001 to 2010, an average of 120 cases per year were recorded in the United States (10). Tularemia occurrences are nationally reportable. The highest incidence and disease severity occurs in children 5 to 9 years old and in elderly persons greater than 75 years old (2,11,12).

CLINICAL PRESENTATION

Two main syndromes are currently recognized: ulceroglandular tularemia and typhoidal (systemic) tularemia (2,11,12). All syndromes begin with an incubation period ranging from 2 to 21 days (3 to 6 days on average) and may last 1 to 4 weeks. Patients display abrupt onset of fever, chills, headache, and myalgias. Cough, vomiting, diarrhea, and diffuse arthralgias often occur. Erythema multiforme, erythema nodosum, or other nonspecific, pruritic maculopapular or papulovesicular rash appears on the extremities of 25% of patients 2 weeks after symptom onset (1,2,11).

Ulceroglandular tularemia is the most common tularemic syndrome, comprising 80% of cases and carrying a 2% mortality rate (2,11,12). It is characterized by a solitary skin ulcer at the tick bite site, developing 2 weeks after constitutional symptoms begin. The ulcer is 0.5 to 3 cm in diameter with sharply undermined borders and a flat black or red base. It can evolve into an abscess or necrotic eschar. Fifteen percent of the time, an ulcer does not appear at all; this variant presentation is referred to as glandular tularemia and is twice as likely to occur in children as in adults (1,2). Regional lymphadenopathy always occurs, with possible suppuration or necrosis of the lymph nodes (2,11).

Typhoidal or systemic tularemia constitutes 20% of cases but accounts for 50% of fatalities (11). Patients display the nonspecific febrile syndrome described above, but appear toxic and may progress to overwhelming sepsis. Eighty percent of patients with typhoidal tularemia will develop tularemic pneumonia, which presents with a dry cough, pleuritic chest pain, and dyspnea. Thirty percent of patients with ulceroglandular tularemia develop this condition (12). It is caused by hematogenous spread or direct inhalation of aerosolized bacilli and affects adults 10 times more often than children (12,13).

Complications are usually due to the pneumonic or typhoidal forms and include ARDS, meningitis, pericarditis, endocarditis, hepatic failure, renal failure, rhabdomyolysis, peritonitis, osteomyelitis, DIC, and septic shock (11,12). Infection during

pregnancy can result in premature birth, intrauterine fetal demise, or spontaneous abortion (14).

ED EVALUATION AND MANAGEMENT

Examine the patient thoroughly for the pathognomonic ulcer and regional lymphadenopathy. These findings are present in 60% to 86% of adults, but only 45% of children (1,2,13). Lesions are usually found on the lower extremities in cases of tick bite, with corresponding femoral and inguinal lymphadenopathy, and on the upper extremities in cases of animal handling, with epitrochlear and axillary lymph node involvement. Also check the patient's scalp to avoid missing lesions, especially in children. Oropharyngeal involvement may be seen as a yellow-white oropharyngeal pseudomembrane, and ocular involvement may produce corneal nodules, ulcers, and conjunctivitis (1,2). A pulse-temperature dissociation—bradycardia relative to the height of fever—is pathognomonic for typhoidal tularemia (1,11).

Routine laboratory testing is usually unremarkable although there may be mildly elevated transaminase levels, mild hyponatremia, normal to mild leukocytosis, and thrombocytopenia (1,2,13). Chest x-ray may show the "classic tularemic triad" of ovoid opacities, pleural effusions, and hilar adenopathy or may show a variety of unilobar, multilobar, miliary, or cavitary infiltrates (12,13).

Diagnosis is made by serology or PCR. Culture is insensitive and available only in specially equipped laboratories (11,12).

Start antibiotics while awaiting confirmatory testing, as delaying therapy increases morbidity and mortality (12). Streptomycin, 1 g IM q12h (children 15 mg/kg q12h) for 10 days is bacteriocidal and is the drug of choice (1,2,12,13). Also bacteriocidal, gentamicin is a more widely available alternative at 5 mg/kg/d IM or IV qd (children 2.5 mg/kg q8h) for 10 days (1,2,12,13). These drugs may be used during pregnancy (14). A less effective bacteriostatic regimen is doxycycline, 100 to 200 mg IV or PO q12h (children: 2.2 mg/kg q12h) for 14 to 21 days (1,2). Ciprofloxacin, 400 mg IV or 500 mg PO q12h, for 7 to 14 days; or levofloxacin, 500 mg IV or PO qd, for 7 to 14 days are bacteriocidal, but are not FDA approved for

tularemia and cannot be used in pregnant or pediatric populations (14). Abscesses and infected lymph nodes may need incision and drainage. To avoid corneal perforation, an emergent ophthalmology consult is indicated in cases of ocular tularemia.

DISPOSITION

Admit all patients for parenteral antibiotics. Patients may be switched to oral antibiotics after a few days and discharged if clinically well (1,2,3,12).

Babesiosis

Babesiosis is caused by *Babesia microti,* an intraerythrocytic protozoan. Like the plasmodial agent of malaria, *B. microti* causes red blood cell hemolysis. It is transmitted by deer ticks (*I. scapularis*) in the Eastern and Midwestern United States and by western blacklegged ticks (*I. pacificus*) in the Western United States (2,5). Transmission also occurs via blood transfusion and transplacental infection in neonates (3,5,15). National babesiosis surveillance began in 2011; 1,124 cases were reported across the United States that year (16).

CLINICAL PRESENTATION

The disease spectrum ranges from asymptomatic to mild flu-like illness to severe malaria-like disease to fulminant sepsis. Up to 66% of babesiosis patients are also infected with Lyme disease and these patients are believed to experience more severe symptoms (2,17). Symptom onset follows the tick bite by 1 to 6 weeks and consists of high fever, drenching sweats, fatigue, myalgias, and headache. Rash is uncommon and suggests Lyme coinfection if present. Jaundice and hemoglobinuria may result from parasite-induced intravascular hemolysis (2,16).

All immunosuppressed states, particularly asplenia, are risk factors for severe babesial infection (17). Neonates, the elderly, persons taking immunosuppressive drugs, and persons with cancer, HIV infection, hemoglobinopathies, or chronic cardiopulmonary disease are also at increased risk. The chief complications are ARDS (21%),

DIC (18%), congestive heart failure (12%), and renal failure (6%) (2,16,17). Mortality is 6% to 9% in immunocompetent patients and up to 21% in immunocompromised patients (2,17).

ED EVALUATION AND MANAGEMENT

High fever may be the only physical finding, although 11% to 14% of patients have hepatomegaly or splenomegaly, and 4% have jaundice (2,16,17). Routine blood tests may show leukopenia, thrombocytopenia, or markers of intravascular hemolysis (2,16,17).

Diagnosis is traditionally made by serology or direct microscopy of peripheral blood smears, although greater sensitivity and specificity in acute disease makes PCR the ED assay of choice (1,3,5,17). Babesiosis shares the same tick vector and geographic distribution as HGA and Lyme disease, so coinfection with two or more of these pathogens can occur. Test for all three diseases if babesiosis is suspected (1,2,17).

The most evidence-supported regimen is quinine, 650 mg PO q6h to q8h (children: 8 mg/kg q8h), plus clindamycin, 600 mg PO or IV q8h (children: 7 to 10 mg/kg IV q8h), for 7 to 10 days (1,2,5,17). However, because of the frequency of adverse reactions to these drugs, many experts advocate as first-line therapy atovaquone, 750 mg PO q12h (children: 20 mg/kg q12h), plus azithromycin, 500 to 1,000 mg PO on the first day (children: 10 mg/kg), then 250 mg PO qd thereafter (children: 5 mg/kg), for 7 to 10 days (1,2,5,17). Immunosuppressed patients require 6 weeks of antibiotics to prevent persistent parasitemia and relapse (17).

Patients who do not improve within 48 hours of treatment, who have >10% parasitemia (>1% in high-risk individuals), or who have organ failure or massive hemolysis are candidates for exchange transfusion of 8 to 10 units of packed red blood cells (2,5,17).

DISPOSITION

Admit patients with any of the foregoing complications and those belonging to high-risk groups to observe their response to treatment. Discharge well-appearing patients on oral medication and arrange for close outpatient follow-up.

Tick-Borne Relapsing Fever

Tick-borne relapsing fever (TBRF) is caused by spirochetes of the genus *Borrelia,* transmitted by soft ticks (genus *Ornithodoros*), lice, blood transfusion, exposure to infected blood, and transplacental infection of neonates (2,18,19). Patients are bitten by *Ornithodoros* ticks while sleeping in rodent-infested mountain cabins or in the limestone caves of central Texas. TBRF is a notifiable disease only in states abutting the Rocky Mountains, California, and Texas. Together, these states report approximately 25 cases per year (18,19).

CLINICAL PRESENTATION

A 4- to 18-day incubation period (mean, 1 week) is followed by fever, headache, meningismus, myalgias, arthralgias, vomiting, diarrhea, cranial nerve palsies, and a nonspecific maculopapular rash. Symptoms resolve after an average of 3 days, then recur 1 week later. Patients experience an average of two symptomatic and two asymptomatic episodes (2,18,19).

TBRF carries a 15% to 48% perinatal mortality; in utero infection results in severe neonatal sepsis (18,19). No adult deaths have been reported. Other complications include thrombocytopenia, liver failure, renal failure, splenic rupture, myocarditis, pneumonitis, ARDS, encephalitis, meningitis, and visual loss from iritis or endophthalmitis (18,19).

ED EVALUATION AND MANAGEMENT

One-third of patients demonstrate thrombocytopenia and/or hematuria (2,18). Liver enzymes may be elevated. TBRF is diagnosed by microscopic visualization of spirochetes in peripheral blood smears. This is an insensitive method (<70%) as is serology, therefore ED clinicians should obtain blood for PCR (2,18,19).

Doxycycline, 100 mg PO or IV q12h (children: 2.2 mg/kg q12h), for 10 days; erythromycin, 500 mg PO or IV q6h (children: 10 mg/kg q6h), for 10 days; or tetracycline, 500 mg PO or 250 mg IV q6h (contraindicated in children) for 10 days eliminates most relapses

(2,18). A Jarisch–Herxheimer reaction occurs in 50% of patients within 4 to 12 hours of starting antibiotics (18,19). This condition may cause fatal cardiovascular collapse; place affected patients in a critical care unit for hemodynamic monitoring, intravenous fluid resuscitation, and meptazinol therapy.

DISPOSITION

Observe all patients for 4 to 12 hours after initiating antibiotics and discharge the well appearing only afterwards. Admit patients with a Jarisch–Herxheimer reaction to a critical care unit and admit pregnant women and neonates to observe for septic deterioration. Consider admitting infants and very young children.

Colorado Tick Fever

CTF is caused by CTF virus, a coltivirus of the genus *Reoviridae.* Its vector is the Rocky Mountain wood tick *(D. andersonii)* whose habitat extends throughout western North America (2). Blood transfusion-related infections have also been reported (20). CTF is not a CDC-notifiable disease, and only 200 to 400 cases are reported annually in the United States (20,21).

CLINICAL PRESENTATION

CTF is also called *saddleback fever,* for the pathognomonic biphasic fever pattern that occurs in 50% of cases. After a 3- to 14-day incubation period (mean, 5 days), patients present with sudden high fevers, myalgias, and headache. Fevers persist for 2 to 3 days, remit for 2 to 3 days, recur for 2 to 3 days, and then finally resolve. Abdominal pain, nausea, vomiting, diarrhea, meningismus, photophobia, conjunctivitis, pharyngitis, and a nonspecific rash may also occur (1,2,22). Fatalities are rare (1). Complications primarily occur in children and include meningitis and encephalitis (5% to 10%), pneumonitis, myocarditis, hepatitis, epididymo-orchitis, DIC, and gastrointestinal hemorrhage (1,21,22).

ED EVALUATION AND MANAGEMENT

Complete blood count (CBC) may reveal neutropenia and thrombocytopenia (20,21). Diagnosis is made by serology or PCR (1,2,20,21,22). Most patients will not be critically ill, and treatment is purely supportive.

DISPOSITION

The majority of patients will be nontoxic and safe for discharge. Admit patients with complications of CTF.

Differential Diagnosis

The initial presentation of tick-borne illness is nonspecific; this creates a broad differential diagnosis. Each tick-borne illness can suggest one of the other tick-borne illnesses, various viral syndromes, various bacterial sepsis syndromes, bacterial endocarditis, disseminated gonococcemia, typhus, Q fever, tuberculosis, pasteurellosis, or toxoplasmosis. The nonspecific rash resembles that of other tick-borne diseases, various viral syndromes, scarlet fever, Kawasaki disease, toxic shock syndrome, Stevens–Johnson syndrome, or secondary syphilis. Tularemic ulcers and lymphadenopathy suggest bubonic plague, anthrax, sporotrichosis, cat scratch disease, lymphogranuloma venereum, streptococcal or staphylococcal cellulitis, or lymphoma. Lung findings can recall severe acute respiratory syndrome (SARS), hantavirus pulmonary syndrome (HPS), psittacosis, anthrax, or other atypical bacterial, fungal, or viral pneumonia. Neurologic involvement suggests meningococcemia or viral encephalitis. Episodic fever suggests malaria, louse-borne relapsing fever, yellow fever, rat bite fever, brucellosis, or leptospirosis. ED bloodwork may seem consistent with hepatitis, idiopathic thrombocytopenic purpura (ITP), thrombotic thrombocytopenic purpura (TTP), various viral hemorrhagic fevers, or dengue.

KEY TESTING

- Examine patients thoroughly for evidence of ticks, tick bites, and/or tularemic ulcers.

- Order a CBC, serum sodium and liver function tests to help make the diagnosis.
- Order disease-specific PCR or serologic assays to confirm the diagnosis. Test patients simultaneously for HGA, babesiosis, and Lyme disease as they share the same tick vector, and coinfection is common.

Common Pitfalls

- Failure to consider tick-borne disease in patients with nonspecific febrile syndromes, rash, jaundice, and/or neurologic complaints
- Failure to obtain an environmental exposure and blood transfusion history in patients with febrile syndromes
- Failure to obtain a history of symptom patterns in patients with febrile syndromes
- Delaying antibiotic therapy until definitive diagnostic tests (culture, PCR, serology, or peripheral blood smear) are resulted

CHAPTER 188

Tuberculosis

Gregory J. Moran and David A. Talan

Tuberculosis (TB) causes more deaths worldwide than any other single infectious disease. Approximately one-third of all humans are infected with *Mycobacterium tuberculosis*. Approximately 9 million new cases of active disease develop annually, resulting in about 1.4 million deaths worldwide (1).

The incidence of TB in the United States has greatly decreased since the 1950s owing to the introduction of better public health measures and effective anti-TB drugs. Compared to about one third of the world population, only about 3.2% of the United States population is infected with *M. tuberculosis* (2). TB in the United States disproportionately affects immigrants, ethnic minorities, the poor, and homeless populations. Multidrug-resistant strains of *M. tuberculosis* (MDR-TB) have emerged, especially among immigrants and patients with acquired immunodeficiency syndrome (AIDS), and extensively drug-resistant TB (XDR-TB) strains have also been seen (3).

M. tuberculosis is a slow-growing bacterium transmitted between persons by droplet nuclei produced from coughing and sneezing. The small size of the droplets allows them to remain suspended in the air for long periods. Infection can occur if contaminated droplets are inhaled and reach the alveoli. The risk of infection is a function of the level of contamination of the air and the length of time the air is breathed. Small, enclosed areas with poor ventilation are more likely to promote the spread of TB.

M. tuberculosis infection usually begins in the alveoli, where bacilli are able to multiply. Infection spreads through the lymphatics

to regional lymph nodes and subsequently to the bloodstream. In most persons, cell-mediated immunity will develop over 2 to 10 weeks and contains the infection. When this immunity has developed, it is possible to identify *M. tuberculosis* infection with a TB skin test or interferon gamma release assay (IGRA). In this situation, in which the immune system prevents further spread, the person is said to have latent *M. tuberculosis* infection without disease. These people have no clinical symptoms of TB and cannot infect others. Symptomatic disease is referred to as TB.

M. tuberculosis survives within macrophages as a facultative intracellular parasite and thus can remain dormant in the body for many years. Active TB develops within 2 years in about 5% of patients, and another 5% will develop reactivation disease at some later point in life. Reactivation is more likely to occur in people with impaired cell-mediated immunity, such as those with diabetes, renal failure, malnutrition, or immunosuppression. Patients taking tumor necrosis factor (TNF)-antagonists (e.g., infliximab, etanercept, and adalimumab) are at much higher risk for developing active TB.

AIDS patients lack the ability to mount an effective cell-mediated immune response and are thus much more likely to progress to active disease. The risk of latent *M. tuberculosis* infection progressing to active TB in persons infected with human immunodeficiency virus (HIV) is estimated to be 5% to 8% per year, compared with the 5% to 10% lifetime risk for people not infected with HIV (4).

MDR-TB is defined as that due to an organism with in vitro resistance to at least isoniazid (INH) and rifampin, regarded as the two most powerful TB drugs. XDR-TB is defined as TB resistant to at least INH and rifampin, plus resistant to any of the fluoroquinolones (such as ofloxacin or moxifloxacin) and to at least one of three injectable second-line drugs (amikacin, capreomycin, or kanamycin) (3). Factors associated with the presence of MDR-TB include previous treatment (especially patients who were given an inadequate regimen or were not fully compliant), exposure to a known case of MDR-TB, birth or residence in an area of high MDR-TB incidence (Asia and Africa being highest risk), and living in environments such as homeless shelters and prisons, where there

may be a high risk of MDR-TB transmission. HIV-infected patients who are exposed to MDR-TB are at especially high risk of developing the disease.

Several factors contribute to the development and spread of MDR-TB and XDR-TB. One of the most important is incomplete compliance with medications. Failure to take medication as prescribed promotes drug-resistant organisms to develop. The prescribed regimen must contain at least two drugs to which the organism is susceptible. Because susceptibility testing takes several weeks to complete, some patients receive inadequate treatment regimens while susceptibility results are pending. With ineffective therapy, the patient remains infectious to others.

Because patients on inadequate therapy are infectious for longer periods compared to those on adequate treatment, MDR-TB and XDR-TB may have a selective advantage over susceptible strains, which may lead to an increasing incidence of persons with drug-resistant infections. Until more effective therapies or vaccines are available, the best weapon against TB is an aggressive infection control program focusing on early diagnosis, isolation, and directly observed therapy for TB patients.

CLINICAL PRESENTATION

The symptoms of TB vary dramatically, depending on the site and stage of infection and the overall health and immune status of the host. Some patients have mild symptoms that go unnoticed; some can be truly asymptomatic. Such patients can be identified only through exposure history, an abnormal chest radiograph, a positive TB skin or blood test, a positive smear for acid-fast bacilli (AFB), or a positive TB culture.

Early pulmonary TB often causes minimal symptoms. As the disease progresses, patients develop insidious constitutional symptoms such as fatigue, anorexia, weight loss, fevers, and night sweats. Cough progresses slowly over weeks to months, becoming productive of mucopurulent sputum. TB should be considered in any patient at risk who has a cough of more than 2 to 3 weeks' duration.

Hemoptysis due to endobronchial erosion may be present, usually indicating more advanced disease. Some patients present with a more acute onset of fever, chills, cough, and myalgias, similar to an episode of acute bronchitis or pneumonia. Chest findings of rales or consolidation may be present. Patients can have a dull ache or tightness in the chest, or they can have pleuritic pain related to TB pleuritis. Signs of pleural effusion may indicate a tuberculous empyema.

Most cases of disseminated TB have a subacute presentation with systemic symptoms. However, some patients with hematogenous dissemination of TB may present with an acute illness of fever, dyspnea, and cyanosis, mimicking bacterial sepsis. Physical findings can include hepatosplenomegaly, lymphadenopathy, erythema nodosum, and tuberculous lesions visible on examination of the optic fundi. Elderly patients are particularly prone to presenting with unexplained fever and hematologic abnormalities such as pancytopenia or leukemoid reaction.

TB may involve virtually any structure in the body and produce symptoms and signs related to the affected organs and systemic symptoms. In about 15% of TB cases, major involvement is seen at an extrapulmonary site. Granulomatous lymphadenitis is usually caused by *M. tuberculosis* in adults, but nontuberculous mycobacteria are a more common cause in children. The cervical and supraclavicular nodes are the most common sites of infection, but any nodes can be involved. Genitourinary TB can present as recurrent urinary tract infections without the growth of the usual bacterial pathogens (i.e., pyuria without bacteriuria) or simply recurrent fever. Skeletal TB is most common in the spine (Pott disease) and weight-bearing joints and usually presents as fever and localized pain.

Tuberculous meningitis is more common in small children as a complication of initial infection, but it can occur in any age group. TB meningitis typically has a subacute onset and presents as headache, altered mental status, or seizures. Cranial nerve signs attributable to involvement of the basilar meninges can be present. Some patients may have new psychiatric symptoms. The

cerebrospinal fluid characteristically shows a moderate lymphocytic pleocytosis (usually 100 to 500 cells/mm^2), elevated protein, and low glucose. AFB smears and cultures of cerebrospinal fluid are usually negative with TB meningitis, and it is often treated empirically in patients at risk for TB who have an otherwise unexplained meningitis.

HIV-infected patients are especially prone to having atypical presentations of TB. TB usually causes disease at an earlier stage of HIV infection than opportunistic pathogens such as pneumocystis, presumably because TB is more virulent than these other pathogens. Extrapulmonary involvement is much more common in HIV-infected patients with TB, occurring in 40% to 75% of cases, usually with concomitant pulmonary disease. In patients with advanced AIDS, cavitary lung disease and localized extrapulmonary disease are relatively less common, with more typically a diffuse pneumonia mimicking that due to *Pneumocystis jiroveci;* disseminated TB with chronic febrile illness and multiorgan involvement is also more often present (3).

DIFFERENTIAL DIAGNOSIS

Pulmonary TB can potentially mimic many other diseases, including pneumoconiosis, bacterial pneumonia, bronchiectasis, sarcoidosis, lung abscess, neoplasm, and fungal infections such as coccidioidomycosis, histoplasmosis, or pneumocystis. Factors helpful in identifying TB as a cause of illness include history of exposure to TB; characteristic radiographic findings, such as cavitations or apical infiltrates; presence of AFB on sputum smear; and results of skin or blood tests. The diagnosis of TB is ultimately confirmed by the culture of *M. tuberculosis,* but culture may take several weeks.

The possibility of TB should be considered when selecting empirical antibiotics for patients with community-acquired pneumonia. If TB is a possibility, it is advised not to use fluoroquinolones (which are used as second-line TB agents) to avoid the risk of selecting out fluoroquinolone-resistant TB. A regimen

such as ceftriaxone plus azithromycin would be a better choice in this situation.

It may be difficult to distinguish disease due to *M. tuberculosis* from disease due to other mycobacterial species. A number of mycobacterial species other than *M. tuberculosis* have been identified. Many are ubiquitous in the environment and are usually contaminants when isolated, but some have been found to be human pathogens (5). *Mycobacterium avium* complex (MAC) (also known as *Mycobacterium avium-intracellulare*), *Mycobacterium kansasii,* and other mycobacteria are rare causes of pulmonary disease; most other mycobacterial species are associated with skin, soft tissue, and lymph node infections. AFB identified in sputum smears may represent colonization by nonpathogenic mycobacteria, but until they can be definitively identified as such by culture, they should be considered to represent *M. tuberculosis* in a patient with a clinical picture consistent with TB.

MAC is the most common mycobacterial species isolated from persons with AIDS in the United States. Infection typically occurs as a systemic febrile illness in end-stage AIDS patients, rather than as a pulmonary infection in earlier-stage AIDS patients, as with *M. tuberculosis.* A chest radiograph usually does not suggest mycobacterial disease, and pleuritis is uncommon. Acid-fast smears of stool and mycobacterial blood cultures are commonly positive, but acid-fast smears of sputum are often negative, suggesting that the gastrointestinal tract, rather than the lungs, is the portal of entry.

MAC infections in AIDS patients are often difficult to treat effectively, but they may respond to regimens containing clarithromycin or azithromycin, ethambutol, rifabutin, clofazimine, or ciprofloxacin. HIV-infected patients with suspected pulmonary mycobacterial disease should generally be given empiric therapy against *M. tuberculosis* initially. Clarithromycin can be added to the TB regimen for enhanced activity against MAC. Therapy can be adjusted later if MAC or other nontuberculous mycobacteria are cultured.

ED EVALUATION

The most important test in the initial evaluation of patients with suspected pulmonary TB is the chest radiograph. Findings strongly suggestive of pulmonary TB include nodular densities, with or without cavities, which are commonly seen in the apical and posterior segments of the upper lobes or in the superior segments of the lower lobes (Fig. 188.1). Children often have pronounced hilar or mediastinal adenopathy (6).

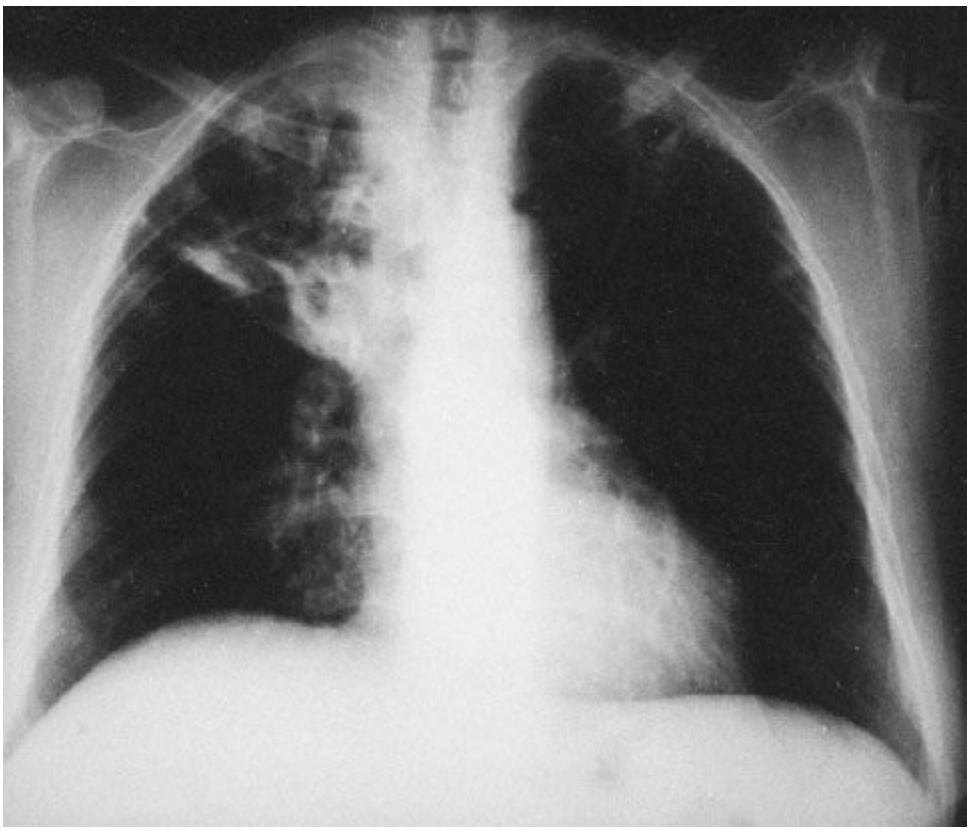

FIGURE 188.1 Chest radiograph demonstrating apical infiltrate with cavitation, typical of pulmonary tuberculosis.

In disseminated TB, the chest radiograph often reveals a miliary pattern, but it can be normal in the early stages. TB has many different radiographic appearances, ranging from normal to lobar consolidation to a diffuse interstitial pattern. Patients with AIDS are especially likely to have TB without the typical radiographic pattern, and they are more likely to have lymphadenopathy on a

chest x-ray. A diffuse interstitial pattern that is easily misdiagnosed as pneumocystis pneumonia may be seen in patients with AIDS (Fig. 188.2).

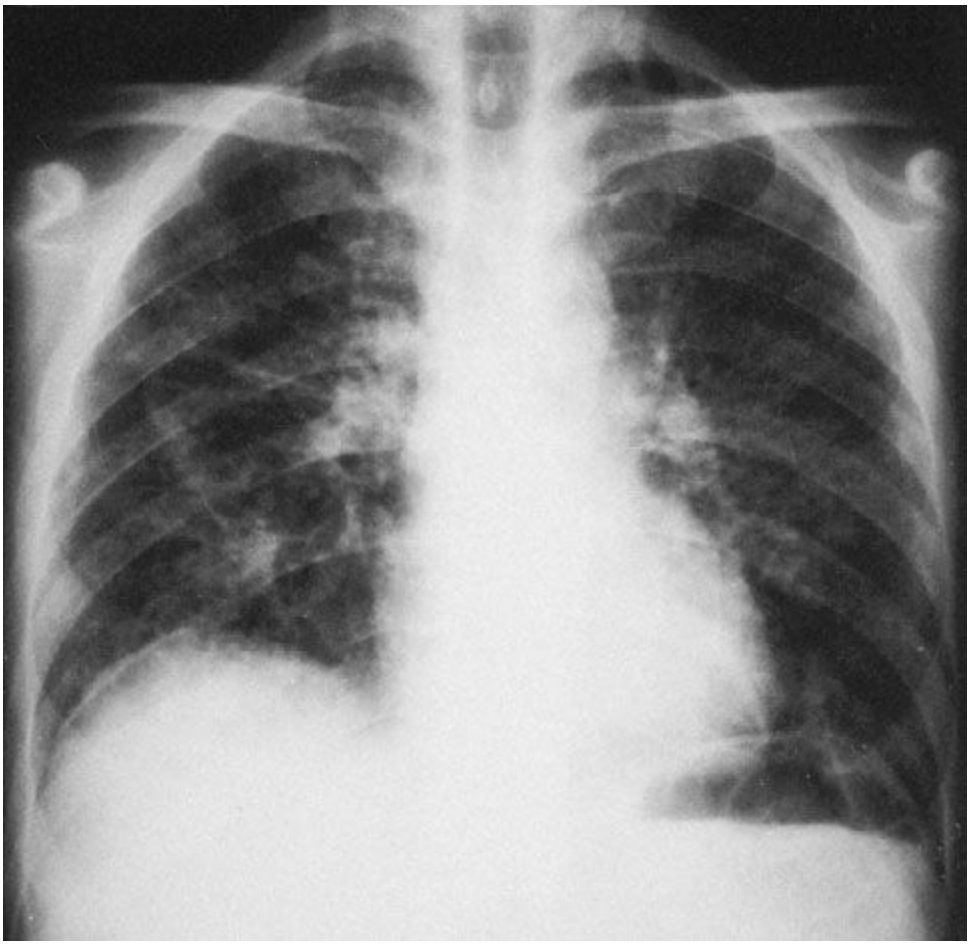

FIGURE 188.2 Chest radiograph of HIV-infected patient with tuberculosis demonstrating hilar adenopathy and scattered interstitial infiltrates. This patient was initially misdiagnosed with pneumocystis pneumonia.

If pulmonary TB is suspected, sputum samples should be obtained for AFB smear and culture. Sputum collection can put health care workers and other patients at risk for exposure to TB and should be performed only in an isolation room adequately equipped with outside ventilation and filters or ultraviolet light. Emergency departments (EDs) may consider having the patient step outside to provide a specimen if these facilities are not available. Ideally, three

successive early-morning sputum samples should be obtained. In certain cases, they can be obtained on an outpatient basis.

A positive AFB smear supports a presumptive diagnosis of TB. A positive smear does not necessarily indicate infection with *M. tuberculosis,* however, because other mycobacteria (e.g., MAC) are also acid-fast. Patients with positive smears are potentially the most infectious because they are usually coughing up large number of organisms. Because culture is more sensitive than AFB smear for the diagnosis of TB, the sample should be sent for culture even if the smear is negative.

AFB smear results are usually not available within the time frame of an ED visit. If there is a high likelihood of TB, the patient can be started on empiric therapy, with further AFB specimens obtained over the next couple of days. Empiric therapy will not significantly affect the diagnostic yield of specimens obtained over the next 1 to 2 days. Delays in diagnosis are a problem with standard techniques because culture usually takes 3 to 6 weeks and susceptibility tests may take 8 weeks. Nucleic acid amplification tests, such as polymerase chain reaction, can rapidly verify *M. tuberculosis* by directly detecting TB-specific DNA sequences. The Centers for Disease Control and Prevention (CDC) now recommends that nucleic acid amplification-based testing should be performed on at least one specimen from patients suspected of TB (7). Advantages of nucleic acid amplification-based testing over traditional AFB smear and culture include greater sensitivity than AFB smear, ability to distinguish TB from nontuberculous mycobacteria in smear-positive specimens, and results in 1 to 2 days rather than weeks required for cultures. A newer molecular diagnostic test can detect TB directly from untreated sputum in less than 2 hours (8).

There are two methods to identify persons infected with *M. tuberculosis:* intradermal tuberculin skin testing (TST) and IGRA. Testing should be targeted at those persons who are at increased risk of recent latent TB infection or with conditions that increase the risk of developing active TB (2,9). Persons for whom testing for latent TB is recommended are listed in Table 188.1, and

interpretation of the TST is summarized in Table 188.2. TSTs or IGRAs cannot distinguish active TB disease from latent TB.

TABLE 188.1
People for Whom Testing for Latent TB Infection is Indicated

People with signs, symptoms, or chest x-ray suggestive of active TB
Recent contacts of people known to have, or suspected of having, active TB
People with HIV infection
People with an abnormal chest x-ray compatible with past TB
People with other medical conditions that increase the risk of TB (e.g., intravenous drug use, diabetes, immunosuppressive therapy, renal failure, rapid weight loss)
Groups at high risk of recent infection with TB, such as immigrants from Asia, Africa, Latin America, and Oceania; medically underserved populations (e.g., homeless); personnel and residents in long-term care facilities and correctional institutions

TABLE 188.2
Criteria for Interpretation of Purified Protein Derivative Skin Tests as Positive

Induration ≥5 mm
Recent contact with someone with active TB
Fibrotic changes on chest radiograph consistent with prior TB
HIV infection
Patients with organ transplants or other immunosuppression
Induration ≥10 mm
Recent immigrants (<5 yrs) from an area with high TB prevalence
Intravenous drug users
Residents or employees of high-risk congregate settings (e.g., prison, nursing home, hospital, homeless shelter)
Mycobacteriology laboratory personnel
Persons with underlying disease that puts them at high risk for reactivation TB (e.g., diabetes, renal failure, malignancy, gastrectomy)
All children <4 yrs, as well as children and adolescents exposed to adults at high risk for TB
Induration ≥15 mm
Persons with no risk factors for TB

Table adapted from Centers for Disease Control and Prevention. Targeted tuberculin testing and treatment of latent tuberculosis infection. *MMWR* 2000;49(No. RR-6):1–51.

The Mantoux skin test is performed by injecting 5 units (0.1 mL) of purified protein derivative (PPD) intradermally. The arm is then examined 48 to 72 hours later for induration at the site. A negative TST does not rule out TB; 60% of AIDS patients and up to 30% of those without HIV infection have a reaction of <5 mm even when they are infected. False-positive reactions may be caused by crossreaction with other mycobacteria, such as MAC. A history of bacille Calmette-Guérin (BCG) vaccination generally does not alter the guidelines for interpretation of the TST, but can make the test less specific for TB infection. BCG vaccination usually does not cause a reaction of >10 mm, and the extent of the reaction decreases with time. Because the vaccine is generally given only in areas with a high incidence of TB, a reaction ≥ 10 mm should still be considered positive in these patients (9).

A newer alternative to the traditional TST are blood tests to detect an immune response to *M. tuberculosis*. In patients with prior or current TB infection, the white blood cells release interferon-gamma (IFN-γ) when exposed to synthetic peptides that simulate antigens

present in *M. tuberculosis*. IGRAs detect IFN-γ release to identify patients with TB infection. When compared to TSTs, IGRAs are more specific for diagnosing TB infection, especially in patients who have previously been vaccinated with BCG. IGRAs do not require a second visit for reading, and are less susceptible to variable results from the reader's interpretation (e.g., erythema vs. induration). TSTs are less expensive so are still used as the first-line diagnostic tool at many institutions. TSTs are generally preferred in children <5 years due to lack of data on IGRA (10).

The CDC recommends that facilities serving persons at high risk for HIV infection, TB infection, or both should provide screening for TB and encourage HIV testing. It is also recommended that TB case finding be part of the regular health care provided to all homeless people. Many persons at risk for TB and HIV come into contact with the health care system only for episodic care in EDs.

ED-based screening for TB could potentially identify many patients who would benefit from treatment. However, the cost and time commitment necessary for an effective TB screening program may preclude the development of such a program in many EDs. If a TB screening program cannot be established in the ED, patients at risk for TB should at least be referred to local public health clinics for testing. It is essential that all persons with suspected infectious TB be reported to local public health authorities (11).

KEY TESTING

- Chest radiograph
- Sputum for AFB smear and culture (collected using adequate respiratory precautions)

ED MANAGEMENT

Preventing the Spread of Tuberculosis

The most important issue in the ED is the rapid recognition of infectious TB patients to prevent exposure of ED staff and other patients. The basic principles for preventing the transmission of TB include early identification of persons with active TB, early

initiation of AFB isolation precautions, and initiation of effective therapy to render the patient noninfectious. Lapses in infection control measures have led to nosocomial transmission of MDR-TB between patients and from patients to health care workers.

The ED is potentially a high-risk area for the transmission of TB because patients may be undiagnosed with TB when they present initially and sometimes are crowded together for long periods, especially in busy inner-city EDs that are likely to have a larger number of TB patients. There may be long delays in recognition and initiation of infection control measures for infectious TB patients in the ED, and HIV-infected patients appear to be even more likely to have delays in recognition because they often have atypical presentations (12).

EDs should consider triage protocols to identify possible TB patients early (13). Those with possible TB should have a mask placed before an expedited chest radiograph.

Once a patient is suspected of having active TB, infection control measures should be initiated (11,13,14). These measures are aimed at isolating the source from other patients and reducing the microbial contamination of indoor air. Recommendations include the use of a private room for the source patient with negative pressure in relation to surrounding areas and a minimum of six air exchanges per hour. Air from the room should be exhausted directly to the outside. Use of ultraviolet lamps and/or high-efficiency particulate air filters to supplement ventilation may be considered.

Many EDs do not have the facilities to comply with these recommendations, and the costs associated with fitting a department with such facilities are substantial. If facilities that meet these standards are not available, it is important to at least designate an area for persons with possible TB that will keep them isolated from other patients and will minimize air exchange with other patient areas. Placing an ordinary surgical mask on the patient may help reduce the amount of airborne droplets produced with coughing, but they are not completely effective for preventing the transmission of TB when worn either by TB patients or by those at risk for exposure. Masks used in the conventional manner are not designed

to filter out particulates in the 1- to 5-μ range and can leak large amounts of air around the edges. The CDC recommends that health care workers use masks capable of filtering out at least 95% of particles in the 1-μ range (commonly designated as N-95) for protection against TB.

Respiratory isolation for possible TB should be considered for higher-risk pneumonia patients admitted to the hospital, but most facilities do not have enough isolation rooms for all pneumonia cases. A prospectively validated ED decision instrument was found to have 99.7% negative predictive value for TB in pneumonia patients with no TB history, no previous positive TB skin test, nonimmigrant, not homeless, not recently incarcerated, no recent weight loss, and no apical infiltrate or cavitary lesion on plain chest radiograph (15). AIDS patients with pneumonia of any radiographic appearance are at such increased risk of TB (and delayed recognition) that routine respiratory isolation is recommended. AIDS patients with compatible respiratory and constitutional symptoms and negative X-ray should be considered for chest computed tomography to exclude pulmonary TB.

Treatment of Active Tuberculosis

Initiation of an effective drug regimen is important to prevent the spread of TB, but it is usually not critical to begin treatment immediately in the ED. Presumptive therapy can begin in the ED on the basis of clinical grounds alone if the patient is at risk for TB and has signs, symptoms, and radiographic findings strongly suggestive of TB. Specimens should still be sent for AFB smear, culture, and sensitivity for subsequent management. If cultures are negative or yield only nontuberculous mycobacteria, treatment can be stopped or adjusted accordingly.

Active TB should always be treated with at least two drugs to which the organism is susceptible. Administration of a single drug can lead to the development of a bacterial population resistant to that drug. When two or more drugs are used simultaneously, each helps to prevent the emergence of TB resistant to the other. Because

of concern about MDR-TB, recommended initial therapy for TB includes four drugs. The preferred initial regimen consists of daily rifampin, INH, pyrazinamide (PZA), and ethambutol (often abbreviated as RIPE) (1,3,16). Doses of these drugs can be found in Table 188.3. If four drugs are used in the initial regimen, it is very likely that the organism will be sensitive to at least two of them. The initial regimen is continued for 2 months, at which time the number of drugs and frequency of dosing can be reduced, depending in part on the results of susceptibility testing.

TABLE 188.3
Daily Dosage Recommendation for the Initial Treatment of Tuberculosis

Drug	Children <12 yrs	Adults
Isoniazid	10–15 mg/kg Max 300 mg	5 mg/kg Max 300 mg
Rifampin	10–20 mg/kg Max 600 mg	10 mg/kg Max 600 mg
Rifabutin	Unknown	5 mg/kg Max 300 mg
Pyrazinamide	15–30 mg/kg Max 2 g	15–30 mg/kg Max 2 g
Ethambutol	15–20 mg/kg Max 1 g	15–20 mg/kg Max 1,600 mg

Adapted from Centers for Disease Control and Prevention. Treatment of tuberculosis, American Thoracic Society, CDC, and Infectious Diseases Society of America. *MMWR* 2003;52(No. RR-11):1–77.

Immunocompetent patients usually cease to be infectious within 2 to 4 weeks of starting therapy, assuming the infecting organism is susceptible to the drugs being used and the patient is compliant. Treatment should be continued for at least 6 months in immunocompetent persons. Expert advice should be sought if a patient is suspected of having MDR-TB. Alternative regimens using > four drugs may be recommended for these patients, including drugs such as cycloserine, ethionamide, amikacin, linezolid, and

quinolones. Those who are at especially high risk for MDR-TB include anyone with HIV infection, those with known exposure to MDR-TB, and persons from a geographic area or demographic group with a high incidence of MDR-TB.

Expert consultation should be sought before initiating TB treatment for HIV-infected individuals taking antiretroviral drugs due to the potential for drug interactions (especially with rifampin). Patients coinfected with TB and HIV who have low CD4 counts are at high risk of developing immune reconstitution inflammatory syndrome (IRIS) with initiation of antiretroviral therapy. For that reason, antiretroviral drugs are often held until after TB treatment has been started. IRIS due to known or undiagnosed TB coinfection should be considered in patients who present with worsening symptoms within weeks after starting antiretroviral treatment.

Recommendations for treatment of extrapulmonary TB are generally the same as for pulmonary TB. However, longer courses of 9 to 12 months are usually recommended for TB meningitis, bone or joint TB, or children with miliary TB (1,16). Corticosteroids may be a useful adjunct for tuberculous meningitis or pericarditis.

Common side effects of these medications include hepatitis (INH, rifampin), peripheral neuropathy (INH), optic neuritis (ethambutol), and rarely, purpura (rifampin). Adults should have baseline measurements of hepatic enzymes, bilirubin, serum creatinine or blood urea nitrogen, complete blood count, and platelet count. Serum uric acid should be measured if PZA is used, and a baseline examination of visual acuity should be obtained for patients to be treated with ethambutol.

Patients should be instructed to report any symptoms suggestive of hepatitis or thrombocytopenia. Pyridoxine (10 to 50 mg/d) can be given with INH to persons with conditions in which neuropathy is common, such as diabetes, alcoholism, or malnutrition. The rate of adverse reactions to antituberculous agents increases with age and also appears to be higher in HIV-infected patients. Treatment interruption is generally recommended for patients who develop elevation of alanine aminotransferase (ALT) more than three times

the upper limit of normal in the presence of hepatitis symptoms, or more than five times elevated in the absence of symptoms (17).

Management of Tuberculosis Exposure

Management of persons (including health care workers) exposed to others with active TB involves consideration of the likelihood of the following: (a) the exposed person has been newly infected with *M. tuberculosis,* (b) the infecting strain is drug resistant, and (c) the newly infected contact will develop active TB. Contacts who do not have a history of a positive TST or IGRA should receive one of these tests and, if indicated by symptoms, a chest radiograph and sputum examination. Exposed persons who have a positive IGRA or a TST reaction equal to 5 mm should be considered newly infected and should be considered for preventive therapy once active TB has been ruled out.

Persons with a high-risk exposure and a negative TST or IGRA should have a follow-up test 12 weeks after the exposure has ended; if the test is still negative at that time, no further evaluation is necessary. Because the risk of developing TB is higher for young children, preventive therapy may be considered for all children younger than 5 years of age who are close contacts of TB cases until repeat testing is done at 12 weeks after exposure.

Persons who are known to be HIV-infected or otherwise immunosuppressed and who are close contacts of patients with infectious TB should be carefully evaluated for evidence of TB. If there are no findings suggestive of active TB, preventive therapy with INH may be recommended, even if TST is negative (9).

Management of Positive Tuberculosis Skin Tests

Persons with a positive TST or IGRA should be evaluated for the presence of active TB with a chest radiograph. If the chest radiograph is abnormal or if symptoms suggest TB, an examination of sputum for AFB smear and culture is indicated. Those with no evidence of clinical disease should be referred for consideration of preventive therapy for TB. It is not necessary to initiate therapy

urgently in this situation, but it is important that patients understand the importance of follow-up to obtain preventive therapy. It has been shown in numerous studies that preventive therapy substantially reduces the risk of latent infection progressing to clinical disease. Immunocompetent persons who are not at risk for MDR-TB are generally treated with INH for 6 to 9 months (2). Routine laboratory monitoring is not necessary for most patients receiving INH but should be considered for those with HIV, pregnancy, liver disease, or regular alcohol use.

The effectiveness of preventive therapy for people exposed to MDR or XDR-TB strains has not been prospectively studied, and guidelines for management of such patients are less clear. Consultation with local infectious disease experts familiar with local patterns of resistance and current treatments is recommended. Because the efficacy of drugs other than INH and rifampin for preventive therapy is unknown, persons on alternative therapies should have regular follow-up.

Recommendations for TB therapy are likely to continue to change because of shifting patterns of infection and drug resistance. The most current recommendations can be found in *Morbidity and Mortality Weekly Report* and the publications of the American Thoracic Society.

CRITICAL INTERVENTIONS

- Initiate infection control measure for patients suspected of TB.
- Treat active TB with at least two drugs to which the organism is susceptible. Initial treatment usually consists of four drugs (INH, rifampin, PZA, and ethambutol) pending susceptibilities.

DISPOSITION

Considerations for hospital admission include severity of illness, diagnostic uncertainty, and ability of the patient to avoid transmitting infection to others and to comply with outpatient treatment. Criteria for admission of patients with TB are similar to those for patients with other types of pneumonia. Patients who are

not seriously ill and are not immunocompromised can safely be sent home with close follow-up, but precautions must be taken to avoid the spread of TB to others. Any patient who is discharged home with possible TB must be reported to local public health authorities. It can be assumed that household contacts have already been exposed and will need to be tested.

Patients should be instructed to avoid crowded, enclosed, public areas and to wear a mask for at least the first 2 weeks of therapy to reduce the amount of airborne droplets produced by coughing. Other factors, such as homelessness, degree of compliance with medications, follow-up, and compliance with infection control measures should be considered when making decisions regarding admission. In the United States, laws vary among the states in regard to forced treatment and quarantine of patients who will not cooperate with therapy and are believed to be a public health hazard (18).

Common Pitfalls

- Failure to consider the possibility of TB in a patient presenting with nonspecific systemic complaints
- Failure to rapidly initiate infection control measures for patients suspected of TB
- Risking the spread of TB in the ED by performing high-risk procedures such as sputum induction in infectious TB patients without proper isolation procedures
- Failure to isolate AIDS patients with TB because of misdiagnosis as *P. jiroveci* (pneumocystis) or other infections
- Failure to refer patients at risk of latent TB for TST or IGRA
- Failure to recognize and follow up patients whose cultures may become positive several weeks after an ED visit
- Failure to report persons with suspected TB to local public health authorities

CHAPTER 189

Infectious Mononucleosis

David A. Jerrard

Infectious mononucleosi is clinically defined by the triad of fever, lymphadenopathy, and pharyngitis, combined with the development of heterophil antibodies and atypical lymphocytosis. It is caused by the Epstein–Barr virus (EBV), which is also strongly implicated in the etiology of nasopharyngeal cancer and Burkitt lymphoma. The causative organism for this disease remained unidentified until the 1960s. The virus is a member of the herpes virus family. It is a DNA virus that has the ability to become latent after an active infection. The most characteristic feature of the disease is its predilection for the young adult population, especially the 15- to 30-year age group (1). A vaccine against EBV infection is in clinical trials (2).

Epidemiologic studies have shown the presence of antibody to EBV (indicating exposure) correlates strongly with immunity, and its absence is highly indicative of susceptibility (1). The age at which individuals develop the infection depends on socioeconomic factors as well as hygiene. Most children in developing countries have been exposed by the age of 3 years, but only 50% of those in economically advanced countries have antibodies by adolescence. Primary EBV infection during childhood is usually subclinical (1). In many college populations, 30% to 75% remain seronegative (2). By adulthood, most individuals are seropositive.

Epidemiologic and laboratory evidence indicates that transmission occurs through the oropharyngeal route, via saliva (3). EBV may be found in throat washings many months after clinical symptoms have abated and may even be cultured from 10% to 20% of completely asymptomatic individuals. Most transmissions occur from

asymptomatic individuals to previously uninfected members of the population. There have been reports of EBV being found in genital secretions, suggesting a possible role of sexual transmission in adults (4).

When EBV is transmitted by saliva, the initial site of replication is in the oropharynx. Both B lymphocytes and oropharyngeal epithelial cells have specific surface receptors for EBV, and replication takes place within these cells. Both humoral and cellular components are important in the immune response to EBV infection. The cellular response, consisting of the elaboration of T lymphocytes having very similar characteristics to suppressor-cytotoxic T lymphocytes, is responsible for controlling B-cell proliferation (5).

CLINICAL PRESENTATION

The incubation period is 4 to 8 weeks (1). Humans are the only known reservoirs. Nonspecific symptoms such as malaise, anorexia, fatigue, and chills often herald the illness and are followed by the development of fever, pharyngitis, and lymphadenopathy. Most patients seek medical care because of sore throat, but headache and myalgia are often complaints as well. Abdominal pain is rare in the absence of splenic rupture.

Pharyngeal exudate is present about one-third of the time, and palatal petechiae may be observed. Anterior or posterior cervical lymphadenopathy is reported in about 90% of patients and tends to be particularly impressive in these areas. Generalized adenopathy is often present. The nodes may be moderately tender or painless (6). Most clinical and laboratory findings will resolve after 30 days. Cervical adenopathy and fatigue may persist (6).

Splenomegaly is noted in about 50% of patients, mostly in the second or third week of illness, and is usually not associated with pain. The spleen becomes infiltrated with large amounts of lymphoid cells with resultant thinning of the splenic capsule and trabeculae. The presence of pain should alert the clinician to the possibility of impending or actual splenic rupture, an uncommon but well-documented complication of the disease that may be life

threatening if not identified and treated promptly (1). The risk of splenic rupture is highest during the second and third weeks of illness, as the increase in size of the spleen is at its peak. The risk is low 4 or more weeks after the infection (7). Though uncommon, rupture is the most prevalent reason for fatalities (8). Though there have been reported cases in which arteriography in combination with embolization has been used, splenectomy remains the most common choice for management (9).

Tonsillitis may occur during any stage of the illness, although it is usually most pronounced during the first 2 weeks of the postprodromal period. Tonsils hypertrophied to the point of "kissing" in the midline are not unusual and do not mandate hospital admission. The distinction between severe pharyngitis and airway compromise is necessary, but tonsillar hypertrophy rarely causes airway compromise (10).

Complications of infectious mononucleosis are rare, but the clinician must be alert to recognize them. Autoimmune hemolytic anemia may appear within 1 to 2 months of initial symptoms. Mild thrombocytopenia develops in approximately half of all cases. The anemia and thrombocytopenia appear to be antibody-mediated and are usually self-limited, lasting approximately 6 weeks (1). Glucocorticoids have been recommended for the treatment of the thrombocytopenia and the hemolytic anemia, but there is little evidence to support their use (1).

A number of neurologic complications of infectious mononucleosis have been described. Cranial nerve palsies (especially Bell palsy) and various forms of encephalitis are the most common. Cerebellar dysfunction and episodes of Guillain–Barré syndrome have been associated with infectious mononucleosis. Yet, typically, less than 5% of patients develop neurologic symptoms (1).

About 90% of patients with infectious mononucleosis have transient elevation of hepatic enzymes, although significant hepatic dysfunction is exceedingly unusual. Observations have been made that correlate between lactate dehydrogenase (LDH) levels and splenic size (11). Roughly half of these patients have mild hepatic tenderness, but hepatomegaly is infrequent. Clinical jaundice may

develop early in the illness, but resolution usually occurs within a few weeks. Subclinical illness that mimics mild viral hepatitis may be caused by infectious mononucleosis.

Although rare, airway obstruction secondary to extreme lymphoid hyperplasia of the tonsils is a potential complication. Airway compromise, as evidenced, for example, by stridor, requires active airway management.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of sore throat is lengthy (Table 189.1). Because several of the entities (e.g., foreign body, retropharyngeal abscess and hematoma, and, rarely, adult epiglottitis) may be associated with airway compromise, it is vital to rule them out as possibilities. Compared with other causes of sore throat, infectious mononucleosis features more prominent systemic complaints.

TABLE 189.1
Differential Diagnosis of Sore Throat

Retropharyngeal abscess
Epiglottitis
Esophageal candidiasis
Peritonsillar abscess
Foreign body
Uvulitis
Pharyngitis (bacterial or viral)[a]
Laryngitis
Cervical adenopathy

[a]Includes infectious mononucleosis.

Generalized lymphadenopathy prompts consideration of other viral illness, AIDS, leukemia, lymphoma, or tuberculosis.

The differential diagnosis of splenomegaly is broad as well. Infectious endocarditis, abscess, and disseminated tuberculosis are all possible infectious etiologies of splenic enlargement. Infiltrative processes such as lymphoma and leukemia must also be included for consideration.

ED EVALUATION

If there is suspicion of adult epiglottitis or retropharyngeal abscess or hematoma, a soft-tissue lateral radiograph of the neck should be performed. In any patient presenting with the complaint of sore throat, indications of airway compromise should be sought.

The diagnosis of infectious mononucleosis is based on clinical, hematologic, and serologic criteria. In a patient strongly suspected of having infectious mononucleosis, certain laboratory features may aid in making a firm diagnosis.

Common laboratory findings include marked lymphocytosis (greater than 50%) (1). The lymphocytosis is characterized by the presence of cells, roughly 10% of the total with atypical morphology. They are larger than mature lymphocytes, have large lobulated or indented nuclei, and have vacuolated or bluish cytoplasm. The finding of at least 10% atypical lymphocytes on a peripheral blood smear has a sensitivity of 75% and a specificity of 92%, respectively, for the diagnosis of infectious mononucleosis (1). Lymphocytosis usually peaks in the second or third week of illness.

Atypical lymphocytosis may be seen in other infections, such as toxoplasmosis, rubella, mumps, and hepatitis (1). Complicating matters further, mononucleosis-like syndromes may be associated with cytomegalovirus infection, toxoplasmosis, and hepatitis A and B. Sometimes these syndromes cannot be distinguished clinically from infectious mononucleosis due to EBV.

Because so many of the symptoms of infectious mononucleosis are nonspecific, serologic evidence may be required to make the diagnosis. Heterophil antibodies (antibodies that react with antigens not responsible for their production) are characteristically produced in infectious mononucleosis (1). The Monospot test is based on this tube dilution principle.

Because many individuals are heterophil antibody negative during the first week of illness, it seems reasonable to omit this test in patients with an illness of recent onset, unless the physical examination raises a high suspicion for mononucleosis. Patients

should be instructed to return for testing if symptoms persist beyond 7 days.

Individuals with infectious mononucleosis produce specific antibodies directed against EBV antigens. Even though the development of detectable heterophil antibodies may be delayed, EBV antibody tests are rarely necessary, because 90% of cases are heterophil positive, and false-positive heterophil results are rare. Illness is usually mild and self-limited) (1). It should be noted, as with heterophil antibodies, antibodies specific to EBV may sometimes not be detectable until several weeks after the onset of illness. Assays specific for antibodies to EBV are the most expensive modality for diagnosing infectious mononucleosis (12).

KEY TESTING

- CBC—marked lymphocytosis often present
- Monospot test

ED MANAGEMENT

The treatment of infectious mononucleosis usually consists of supportive care. There is no specific antiviral therapy. Fever and pharyngeal pain may be ameliorated by acetaminophen. Aspirin should be avoided because of the risk of increasing bleeding tendency due to thrombocytopenia. Adequate rest should be advised, although rest does not seem to expedite recovery. Ampicillin, via an unknown mechanism, causes a rash in roughly 90% of those with infectious mononucleosis. When treating presumed streptococcal tonsillitis in patients with infectious mononucleosis, erythromycin, or penicillin should be prescribed instead of ampicillin. Splenic rupture is rare after 3 weeks of symptom onset. A recent review suggests a return to contact sports after this period of time, once fever and symptoms have abated (13). Patients should be advised that feelings of malaise may linger, sometimes for months.

Severe pharyngitis may be treated with corticosteroids (prednisone, 40 to 60 mg/d, and tapered over 7 to 10 days).

Impending airway obstruction or an inability to take oral medications may necessitate the use of dexamethasone. Symptoms of dysphagia and difficulty breathing are usually improved within 1 to 2 hours of administration of parenteral corticosteroids. Active airway management is rarely necessary. Although corticosteroids do not decrease spleen size or reduce the likelihood of splenic rupture, some benefit may be obtained in decreasing neurologic, hematologic, and cardiac complications. Corticosteroid therapy is not generally recommended for uncomplicated infectious mononucleosis (14).

In patients presenting with abdominal pain, a computed tomography (CT) scan should be performed. Infectious mononucleosis may be the most common reason for splenic rupture (12). Splenic rupture is unlikely to occur in the first 2 weeks of the illness because the capsular and trabecular changes that permit rupture to occur do not develop for 2 to 4 weeks.

CRITICAL INTERVENTIONS

- Perform a soft-tissue lateral radiograph of the neck for suspicion of adult epiglottitis, retropharyngeal abscess, or hematoma.
- Advise avoidance of contact sports for 2 to 6 months after the onset of illness or until there is absence of splenomegaly on follow-up imaging studies (CT and ultrasound) because of risk of splenic rupture.
- Treat severe pharyngitis with corticosteroids.

DISPOSITION

Most patients with infectious mononucleosis do well without any intervention and can be discharged from the emergency department with instructions to return should abdominal pain develop and breathing or swallowing become difficult.

Consultation with appropriate specialists is indicated for neurologic or hematologic complications.

Patients who are unable to maintain oral intake because of difficulty in swallowing or patients who may have possible airway

compromise should be admitted and should begin parenteral corticosteroids.

In the unlikely event of splenic rupture, a surgical consult is imperative. If either CT scanning or surgical backup is not available, the patient should be immediately transferred to a center that has these resources.

Common Pitfalls

- The differential diagnosis of sore throat includes more than simple viral or bacterial pharyngitis. Other infections localized to the throat can have disastrous consequences if they go undetected. These infections include retropharyngeal abscess and epiglottitis.
- Errors in management are usually the result of a failure to examine the patient thoroughly. This error may result, for example, in a failure to diagnose splenic rupture (spontaneous is more common than posttraumatic), an uncommon but potentially dangerous complication.
- Patients should be advised to seek medical attention promptly if they develop difficulty breathing or abdominal pain.
- Ampicillin should be avoided because of the high likelihood that a rash will develop. The rash is morbilliform and develops 5 to 9 days after the antibiotic is started.

CHAPTER 190

Influenza

Jonathan S. Olshaker

More people died in the 1918 influenza pandemic than in all of World War I. Today, influenza remains a major killer and causes more morbidity and mortality than the acquired immunodeficiency syndrome (AIDS). In nonpandemic years, 20,000 to 40,000 persons die of influenza-related illness in the United States alone (1); in pandemic years, deaths can exceed 100,000. Influenza infections account for tremendous health care expenditures each year. The Centers for Disease Control and Prevention (CDC) estimates that there are between 114,000 and 146,000 hospitalizations per year, with the highest rates of both hospitalization and death being among the elderly and in children younger than 2 years old (2,3).

Influenza is caused by large RNA viruses belonging to the myxovirus groups. Of the three immunologically distinct groups (A, B, and C), influenza A and B are encountered most frequently. Group A is responsible for the majority of the mortality and significant morbidity. It appears to cause more severe disease than type B, making secondary bacterial infection more likely, and is more common in older populations. The disease is spread by large-particle respiratory droplet transmission through coughing or sneezing. The typical incubation period is 1 to 4 days. Adults can be infectious from the day before symptoms begin through 5 days after illness onset. Children can be infectious for more than 10 days after symptom onset.

CLINICAL PRESENTATION

Influenza is an extremely common respiratory illness, characterized by the abrupt onset of fever, sore throat, headache, myalgias, and nonproductive cough. The malaise is often much more extreme than that seen with most other common respiratory illnesses. During an influenza outbreak, influenza can be diagnosed by clinical criteria with a high degree of certainty, with exceptions being in the elderly and in very young children. Young children can present more atypically, often with otitis media, nausea, vomiting, and less prominent respiratory symptoms. In addition, they can present with febrile seizures and symptoms mimicking bacterial sepsis. Symptoms last from a few days to a week in most patients. More severe illness can result if there is pulmonary involvement due to primary viral or secondary bacterial pneumonia, which is the most common cause of death. The vast majority of severe disease occurs in the elderly, the immunosuppressed, patients with chronic cardiovascular or pulmonary disease, and in young children. In addition, pregnancy can increase the risk for serious complications from influenza.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of influenza includes the myriad respiratory and infectious diseases seen in the emergency department (ED). The clinician's major task should be to recognize serious illness that requires specific antibiotic treatment or other aggressive interventions.

Prominent severe headache, meningeal signs, or changes in mental status make it mandatory to rule out meningitis. Sore throat, often seen with influenza, may be due to peritonsillar abscess, epiglottitis, or streptococcal pharyngitis. Myalgia may be due to bacteremia or sepsis, particularly in the elderly. A finding of hypotension or marked orthostasis mandates evaluation for sepsis or toxic shock syndrome, particularly if there is evidence of multiple organ system involvement. Cough or difficulty breathing may be due to bacterial or viral pneumonia, acute bronchospasm, or cardiac processes such as congestive heart failure or myocardial ischemia.

Unfortunately, the differentiation of viral from bacterial pneumonia in the patient with influenza is difficult. Antibiotics should be instituted early if there is any suspicion of a bacterial process.

In the spring of April 2009, an outbreak of H1N1 influenza A virus was observed in many countries, including the United States. In June 2009, the World Health Organization raised its pandemic alert to the highest level, indicating widespread transmission of the disease. The pandemic was not declared to be over until August 2010. In the past few years another major public health concern is the possibility of avian influenza turning into a pandemic. Avian flu is an influenza A virus found chiefly in birds, but isolated human cases have been found in Asia, parts of Europe, the Middle East, and Africa, usually after direct contact with infected poultry. In late March and April 2013, human cases of novel avian influenza A H7N9 infection in China were reported to the World Health Organization. The reported case fatality rates have been alarmingly high, exceeding 50%. Current seasonal influenza vaccines provide no protection against human infection with avian influenza A viruses (4).

ED EVALUATION

The initial evaluation of influenza and influenza-like illness should focus on assessment of the airway, breathing, and circulation. Pulse oximetry is a simple noninvasive test that may provide a quick indication of respiratory compromise. Physical examination should focus on the heart and lungs. A thorough examination of the skin should include a search for any cutaneous manifestations of infectious disease, such as purpura or petechiae.

Patients with significant cough, respiratory symptoms, or abnormalities on lung examination should have a chest radiograph. Lumbar puncture and urinalysis may be indicated if suggested by appropriate symptoms. A complete blood cell count, though nonspecific, may lend support to a diagnosis of superimposed bacterial infection. Tests to determine levels of electrolytes, blood

urea nitrogen, creatinine, and blood glucose should be ordered in those patients with severe derangements of fluid balance or in those who have chronic medical problems or take medications, such as diuretics, that can affect electrolyte balance. Arterial blood gas analysis and serum lactate may be appropriate when hypoxia or sepsis is suspected. Blood cultures should also be obtained if sepsis is a possibility.

Rapid ED influenza tests are readily available. They are immunoassays that can identify influenza A and B viral nucleoprotein antigens in respiratory specimens. Unfortunately, their poor sensitivity limits their usefulness, particularly in high-risk individuals (5). In a meta-analysis of 159 studies that evaluated rapid antigen tests, the pooled sensitivity was 62.3% and the pooled specificity was 98.2% (6). The sensitivity was lower in adults than children and higher for influenza A than influenza B. Thus, a negative result should be interpreted with caution and treatment should not be delayed in high-risk individuals if influenza is suspected. Small studies have shown that awareness of a positive rapid influenza test result in pediatric ED patients can reduce the number of laboratory tests and radiographs, decrease antibiotic use, and increase the use of antiviral drugs (7,8).

Reverse transcriptase polymerase chain reaction (RT-PCR) is the most sensitive and specific test for a relatively rapid identification of influenza. Its use in the ED is still limited because results may not be available for 4 to 6 hours or even longer.

In the past, viral culture has been considered the gold standard for laboratory diagnosis, but results often take 4 to 12 hours and limit any benefit for initial clinical management.

KEY TESTING

- CXR if significant respiratory symptoms
- CBC for suspected superimposed bacterial infection
- Electrolytes, BUN, creatinine, glucose if dehydrated
- Influenza diagnostic testing (rapid or PCR) to confirm diagnosis

ED MANAGEMENT

The initial treatment for patients with suspected influenza is directed at ensuring adequate oxygenation and hemodynamic stability. Patients with viral or bacterial pneumonia, particularly the elderly or those with chronic obstructive pulmonary disease, can present in extremis with an immediate need for endotracheal intubation and mechanical ventilation. Supplemental oxygen should be given to patients with significant respiratory symptoms or low pulse oximeter readings. Although it is not viewed as standard of care, one study showed that referral to a center where extracorporeal membrane oxygenation was available reduced mortality among patients with severe 2009 influenza H1N1 infection (9).

Patients who are tachycardic, hypotensive, or orthostatic should have a large-bore intravenous line placed and receive initial fluid resuscitation with normal saline. Care should be taken to avoid overhydration, particularly in the elderly or in those with a history of congestive heart failure. Standard bronchodilator therapy is indicated for any accompanying reactive airway disease.

If the patient has a coexisting pneumonia, antibiotics should be instituted in the ED, because it is, as a rule, difficult to differentiate viral pneumonia from bacterial pneumonia. Antibiotics should provide adequate coverage against *Haemophilus influenzae* and group B *Streptococcus,* as well as *Staphylococcus aureus,* which is a relatively common bacterial pathogen associated with influenza outbreaks.

The antiviral agents rimantadine and amantadine previously were found to be effective in reducing the severity and duration of illness in high-risk individuals who had not been vaccinated. However, neither is currently recommended by the CDC for influenza treatment or prophylaxis because of high rates of resistance and side effects.

The Food and Drug Administration has approved a new class of antiviral drugs, neuraminidase inhibitors. Neuraminidase permits the virus to penetrate the surfaces of cells and is necessary for

optimal release of virus from infected cells. Inhibitors now available are oseltamivir, given orally, and zanamivir, inhaled through the mouth at a high flow rate. These agents are approved for the treatment of influenza in patients who have been symptomatic for less than 2 days. Initial studies showed only a 1- to 1.5-day decrease in the duration of symptoms, but subsequent research has supported further benefits and indications for these drugs. Both drugs have been shown to be effective in significantly reducing time to alleviation of symptoms, in prophylaxis for close contacts, and in reducing complications in high-risk individuals especially when the drugs are administered within 48 hours of onset of symptoms (10,11). Zanamivir was associated temporally with the termination of a nursing home outbreak that amantadine had failed to control (12). A 2011 meta-analysis concluded that oseltamivir reduced respiratory complications by 28% (13). Other meta-analyses have provided contradictory results regarding reduction in influenza-related respiratory tract complications in healthy adults (14).

The adult dose of oseltamivir for treatment of influenza is 75 mg twice daily for 5 days. Oseltamivir is approved for treatment and prophylaxis in those 1 year of age and older. The pediatric dose of oseltamivir is 30 mg twice daily for $\geq$15 kg, 45 mg twice daily for 15 to 23 kg, 60 mg twice daily for 23 to 40 kg, and 75 mg twice daily for $>$40 kg. Treatment should begin within 2 days of onset of symptoms of influenza. The recommended oral dose of oseltamivir for prophylaxis of influenza in adults and adolescents 13 years and older after close contact with an infected individual is 75 mg once daily for at least 7 days. Therapy should begin within 2 days of exposure. Oseltamivir causes nausea and vomiting in about 10% of treated persons, although most continue taking the drug. When taken with food, the incidence of gastrointestinal side effects is reduced. Transient neuropsychiatric events including self-harm and delirium have been reported after oseltamivir use.

Zanamivir is approved for the treatment of those 7 years of age and older and the prophylaxis of those 5 years of age or older. The dose of zanamivir for treatment of influenza in adult and pediatric patients aged 7 years and older is two inhalations (one 5-mg blister

per inhalation for a total dose of 10 mg) twice daily (approximately 12 hours apart) for 5 days. Prophylaxis is two inhalations once daily. Zanamivir should be used cautiously in patients with chronic respiratory disease because it can cause bronchospasm and reduction in airflow. A small percentage of patients have difficulty using the inhaler. Understanding proper use should be ensured. The intravenous formulation of zanamivir is being evaluated in clinical trials and is available for compassionate use from its manufacturer.

Treatment with the neuraminidase inhibitors is recommended for the following:

- All patients with high-risk factors (elderly, immunosuppressed, diabetics, adults, and children with other chronic diseases)
- Patients with severe influenza including lower respiratory tract infection
- Pregnant women and women up to 2 weeks postpartum
- Adults 65 years of age and older
- Residents of nursing homes and other care facilities
- Consider for other patients

Prophylaxis recommendations for the neuraminidase inhibitors are as follows:

- Give to high-risk patients who have not been vaccinated.
- Consider for immunosuppressed patients who have been vaccinated.
- Give to high-risk vaccinated patients who received vaccine in poor-match years.
- Give once daily × 6 weeks in season.
- Give × 14 days or until 7 days after onset of last case in nursing home outbreaks.

CRITICAL INTERVENTIONS

- Ensure adequate oxygenation.
- Provide for staphylococcal coverage when treating pneumonia.
- Initiate neuraminidase inhibitors for high-risk patients with influenza.

- Administer influenza vaccine from late September through December to patients at risk for influenza complication and groups capable for influenza transmission.

DISPOSITION

The majority of patients with influenza can be treated as outpatients. Close follow-up should be ensured and the patient should be given specific instructions to return immediately if symptoms progress.

There should be a low threshold for admission for elderly patients, pregnant patients, the immunocompromised, those with chronic pulmonary or cardiac disease, and young children. These patients should be admitted if there is any evidence of pneumonia, which can often progress rapidly. Admission to an intensive care unit should be considered for patients who are hypoxic or show any signs of significant respiratory difficulty.

PREVENTION AND VACCINATION

Influenza vaccines have been shown in numerous studies to be effective in preventing clinical disease (4,15) and extremely cost-effective, especially in persons older than age 65 (16). Each year, a different vaccine preparation is developed, using virus strains believed likely to appear in North America the following winter. The CDC estimated that the effectiveness of the 2012 to 2013 seasonal influenza vaccine in preventing medically attributed infections in all age groups was 56% (4), but as many as 90% of influenza cases can be prevented when there is a good match between vaccine and epidemic strains of the virus (17). Influenza vaccine has also been extremely effective in reducing morbidity and mortality (by up to 80%) in vaccinated individuals who nevertheless develop clinical disease, particularly the elderly and the immunocompromised (18). A number of studies have shown that vaccination reduces influenza-related hospitalizations and deaths in nursing home populations during epidemics (19,20). Also, vaccination clearly lowers cardiovascular mortality and all other case mortality in patients

with cardiovascular disease and other high-risk medical conditions (21). A large 2012 cohort study of community dwelling elderly individuals showed vaccination was associated with a reduction in hospitalizations and death during influenza season (15). The World Health Organization says influenza vaccination may limit the number of false alarms for SARS. Adverse effects of the vaccine itself have been minimal and should not deter its use in the high-risk patient.

Despite the overwhelming evidence supporting the benefits and efficacy of influenza vaccines, many high-risk individuals go unvaccinated. Studies have shown poor vaccination rates in both the elderly and younger persons with high-risk medical conditions such as asthma. Vaccination of health care providers has clearly been shown to decrease mortality in patients (22), but unfortunately the rate of vaccination remains unacceptably low.

Emergency physicians can play a major role in educating patients and the general public about the need for vaccinations in high-risk groups. This should occur before the peak influenza season begins. Target groups for vaccination programs are listed in Table 190.1. Of note, the Advisory Committee on Immunizing Practices of the CDC supports the vaccination of all children older than 6 months and clearly recommends vaccination of children 6 months to 4 years old (23). Vaccinations should be offered between late September and early November, depending on when regional influenza activity is expected to begin. Many EDs offer the vaccine on-site. This approach has been shown to be both needed and feasible (24), even for patients presenting with acute asthma attacks requiring prednisone treatment (25). Emergency physicians are also often in a position to recognize the outbreak of influenza in closed environments such as nursing homes.

TABLE 190.1
Influenza Vaccination Target Groups

Groups at Risk for Influenza Complications

Adults and children with chronic respiratory or cardiovascular disorders
Healthy persons 50 yrs of age or older
All children age 6 mos to 4 yrs
Immunocompromised persons
Pregnant and postpartum patients
People who are morbidly obese

Groups Capable of Influenza Transmission

Residents of nursing homes and chronic care facilities
Physicians
Nurses
Hospital personnel who have close contact with high-risk patients
Home health care or nursing home care providers

Stopping, slowing, or otherwise limiting the spread of an avian flu pandemic has recently become a major focus in the United States and globally. Present efforts are directed at poultry containment, rapid identification of human disease, and limitation of exposure to infected individuals. In addition, there has recently been a heightened focus on vaccine development, improvement in surge capacity, and stock piling of neuraminidase inhibitors, which are felt to be of potential benefit in treating avian flu.

Common Pitfalls

- Failure to recognize that the elderly, the very young, the immunosuppressed, pregnant and postpartum patients, and those with chronic cardiac or pulmonary disease are at high risk for complications from influenza or acute worsening of their baseline chronic disease
- Failure to appreciate that young children can present atypically
- Failure to appreciate the role of *S. aureus* as a pneumonia pathogen during influenza outbreaks
- Failure to start treatment in a high-risk individual because of a negative rapid influenza test
- Failure to be on the alert for nursing home patients with influenza and to notify appropriate officials about potential

outbreaks
- Failure of health care workers to be vaccinated themselves

CHAPTER 191

Human Immunodeficiency Virus Infection and Related Disorders

Richard E. Rothman, Patrick Q. Eckert, and Kamna S. Balhara

The earliest recognition of a new immunodeficiency syndrome, later identified as being caused by the human immunodeficiency virus (HIV), occurred in 1981, with cases of Kaposi sarcoma (KS) and *Pneumocystis carinii* pneumonia (PCP) occurring in previously healthy homosexual males. The complications of infection, known as the acquired immunodeficiency syndrome (AIDS), continue to cause significant morbidity and mortality both in the United States and worldwide. HIV-related therapeutics made dramatic advances in the mid-1990s, with early use of highly active antiretroviral therapy (ART) and prophylactic agents for opportunistic infections. However, the medical, social, and economic impact of this disease continues to grow.

As of 2010, the United States Centers for Disease Control and Prevention (CDC) estimated the total number of people living with HIV in the United States at 1.1 million, with 636,000 Americans having died of the disease (1). Despite widespread efforts to curtail the spread of the virus, approximately 50,000 new infections occur each year, a number that has not changed appreciably in the past 10 years (1).

EPIDEMIOLOGY

The majority of HIV and AIDS cases in the United States have occurred in men, although the proportion of women infected has risen from 8% in 1985 to 25% in 2010 (2). Minority groups are disproportionately affected. As of December 2010, African Americans and Hispanics represented 58% of males and 79% of females living with HIV. AIDS represents the fifth leading cause of death in African American men aged 25 to 44 (3).

Risk factors associated with an increased likelihood of acquiring HIV infection include men who have sex with men, people who exchange sex for money or drugs, intravenous (IV) drug use, and heterosexual exposure to a high-risk partner. Blood transfusion before 1985 and maternal-to-neonatal transmission represent a small minority of cases. The pattern of incident HIV infections is changing. Worldwide, heterosexual contact is the most common route of HIV transmission. In the United States, new infections among men who have sex with men currently represent 63% of new diagnoses. After several years of decline in the early and mid 2000s, this number has begun to increase, related mainly to infections among younger individuals. In addition, heterosexual contact continues to increase as a mode of transmission while IV drug use has been decreasing for the past decade (2). During the past several years, the greatest increase in reported AIDS cases has occurred among women and minority populations. Recently, African Americans and Hispanics represented 65% of incident cases among males and 80% of incident cases among females (2). Because many of the populations at highest risk for disease are underinsured and have limited or no access to primary care, emergency departments (EDs) are caring for increasing numbers of patients with HIV and AIDS.

PATHOPHYSIOLOGY AND TRANSMISSION

HIV is a cytopathic retrovirus that kills infected cells. In humans, HIV appears to selectively attack CD4 T-lymphocytes, a characteristic that accounts for much of the resulting immunodeficiency. The virus attaches to a host cell via specialized receptors on the cell surface. The viral genome, encoded by a single-stranded ribonucleic acid (RNA) molecule, is reverse transcribed into DNA using the enzyme

reverse transcriptase. Viral DNA is then permanently integrated into the host's genome via an integrase enzyme. Once integrated, viral DNA may lie dormant or may be actively transcribed and translated to produce protein precursors. HIV protease then cleaves these precursor molecules to produce functional enzymes that can be encapsulated into new HIV virions.

ART is directed at reducing levels of HIV RNA by interfering with the enzymes integrase (integrase inhibitors), reverse transcriptase (nucleoside and nonnucleoside reverse transcriptase inhibitors [NNRTIs]), and HIV protease (protease inhibitors [PIs]). However, the emergence of mutant drug-resistant strains, the dormancy of the virus in some cells, and the occurrence of drug toxicity limit the ability to permanently stop viral replication.

Proven mechanisms of HIV transmission include exposure to semen, vaginal secretions, blood products, transplacental (in utero), and breast milk. There have been no documented cases of transmission by casual contact, although reports of possible salivary transmission exist (4). The HIV virion is extremely labile and can be easily neutralized by 50% ethanol, 0.3% hydrogen peroxide, or a 1:10 solution of household bleach.

CLINICAL PRESENTATION, ED EVALUATION, AND MANAGEMENT

Acute HIV Infection and Disease Progression

Forty percent to 90% of patients infected with HIV will develop acute retroviral syndrome 2 to 4 weeks after exposure (5). This syndrome is characterized by a range of nonspecific, "flu-like" symptoms, but, significantly, may include mucocutaneous ulcers, generalized lymphadenopathy, hepatosplenomegaly, or a rash (usually macular or maculopapular). The differential diagnosis for acute HIV infection includes Epstein–Barr virus (EBV), cytomegalovirus (CMV), viral hepatitis, syphilis, rubella, disseminated gonococcal infection, and other viral infections. However, the presence of flu-like symptoms in combination with HIV

risk factors or the more specific signs described earlier should increase suspicion for acute HIV infection.

During this acute phase of infection, standard HIV testing (ELISA antibody testing) is usually negative, although newer fourth generation HIV testing technologies narrow the window allowing for detection of acute HIV infections by including antigen detection as part of the testing algorithm (see below). Time from exposure to HIV antibody detection can vary from 2 to 11 months. If standard ELISA HIV antibody testing is negative and there is a high suspicion for acute HIV infection, RNA viral load testing should be performed. A concurrent antibody test for HIV should be performed to establish that an infection is acute and not chronic. Identification of acute HIV infection in the ED, although relatively uncommon, is important because the risk for viral transmission is much greater during this time due to higher viral loads (6). Therefore, patients with diagnosed or suspected acute infection should be counseled to mitigate behaviors that may spread the virus (6). Furthermore, there is some evidence that initiating ART during acute HIV infection may reduce transmission risk, reduce symptoms of acute infection, and reduce disease progression (7). Consequently, a patient with confirmed acute infection should be seen urgently by an HIV specialist.

HIV results in a broad spectrum of conditions, ranging from an asymptomatic infection to severe immunocompromise. Variables that are most predictive of the stage of disease are CD4 cell counts, viral load, and history of opportunistic infections. Clinical findings that are predictive of significant immunodeficiency include thrush, oral hairy leukoplakia, dermatomal varicella, alopecia, wasting, dermatitis, and generalized lymphadenopathy. The diagnosis of AIDS is made by laboratory evidence of HIV infection and either the presence of an “indicator” condition or laboratory evidence of severe immunosuppression (CD4 <200 cells/mm^3) (7). The most recent CDC definition of AIDS published in 2008 is summarized in Table 191.1 (8).

TABLE 191.1
Case Definition of AIDS and Indicator Conditions

1) Laboratory evidence of HIV infection and presence of an AIDS-defining illness
2) Laboratory evidence of HIV infection and CD4 cell count <200/mm^3

AIDS-defining Illnesses:

- Candidiasis, esophageal or pulmonary
- Cervical cancer
- Coccidiomycosis, extrapulmonary
- Cryptococcosis, extrapulmonary
- Cryptosporidiosis (with diarrhea for >1 mo)
- Cytomegalovirus infection (of any organ system other than liver, spleen, or lymph nodes)
- Herpes simplex virus (mucocutaneous ulcer for >1 mo, pneumonitis or esophagitis)
- Histoplasmosis, extrapulmonary
- Isosporiasis (with diarrhea for >1 mo)
- Kaposi sarcoma
- Lymphoma, Burkitt/immunoblastic/primary CNS
- Mycobacterium avium complex or other mycobacterial infection (extrapulmonary)
- Mycobacterium tuberculosis (pulmonary or disseminated)
- *Pneumocystis jiroveci* pneumonia
- Progressive multifocal leukoencephalopathy
- Bacterial pneumonia (recurrent)
- Salmonella bacteremia (nontyphoid)
- CNS toxoplasmosis
- HIV-associated wasting syndrome

Note: The case definition of AIDS is satisfied by either 1 or 2 above. For a more comprehensive list of indicator conditions, refer to the 2008 CDC Case Definition (8).

The average incubation time from initial infection to clinical AIDS is 8 years (7). In the era of modern ART, the burden of chronic disease is increasing in HIV-infected individuals. Reports indicate that mortality in this population from non-AIDS–defining illness may be surpassing mortality from AIDS-defining conditions. Specifically, progressive immunosuppression increases the risk of dementia, cardiovascular disease, cirrhosis (due to alcohol and viral hepatitis), chronic kidney disease, and non-AIDS–defining malignancy (7). In HIV-infected patients admitted to the ICU, *Pneumocystis jiroveci* pneumonia and bacterial pneumonia continue to be significant causes of respiratory failure (9), and septic shock may be associated

with unusual organisms, such as salmonella or *Cryptococcus neoformans,* and a higher risk of adrenal insufficiency (7). Massive gastrointestinal (GI) bleeding can occur secondary to CMV colitis or complications of liver disease, and critical neurologic illness is frequently related to central nervous system (CNS) toxoplasmosis (9).

Median survival time in *untreated* AIDS patients is 3.7 years for patients with CD4 cell counts <200 cells/mm^3, and 1.3 years for patients with a first AIDS-defining illness. Immune reconstitution with ART has been shown to significantly delay progression of opportunistic infections and AIDS-related death.

Diagnosis of HIV Infection

The standard diagnostic test for HIV infection is viral antibody detection with the ELISA. HIV-positive ELISA tests are then confirmed by Western blot (WB), which directly detects viral antigens. Sensitivity and specificity of the current tests are $>99.9\%$. False-negative ELISA tests occur primarily during acute disease before seroconversion. Rates of false-negatives vary according to the prevalence of disease in the population, ranging from $<0.0001\%$ in low-prevalence populations to 0.3% in high-prevalence populations. False-positive tests are less common ($<0.004\%$) and occur among patients who have received transfusions containing HIV antibody or those with other crossreactive antigens or antibodies (e.g., antihepatitis A IgM, antihepatitis B core IgM, and antinuclear antibodies). In children younger than 6 months, a positive test may be due to transplacentally acquired maternal antibodies and does not necessarily imply presence of the disease. False-positive results are most frequent in populations with a low seroprevalence for HIV.

There are a number of rapid HIV tests that are FDA approved, which are simple and easy to use, and which can be implemented at the point of care. These tests use an ELISA-based assay for HIV testing using saliva, fingerstick, or whole blood specimens, and require (as do the traditional ELISA) WB for confirmation. Tests can be performed at the bedside with delivery of results in as little as 10 to 20 minutes. Sensitivity and specificity of these assay is high (e.g., for the saliva OraQuick Rapid HIV-1 Antibody Test [OraSure

Technologies, Inc.], sensitivity and specificity are 99%). Negative tests can be reported as negative.

A new generation of HIV assays has recently been developed. These tests, coined Fourth-Generation (or Combo) HIV assays, test for both HIV antigen and antibody simultaneously, with reflex RNA testing if discrepancies exist between antibody and antigen results. Such platforms shorten the window period for HIV detection by several weeks, permitting diagnosis of very early (acute) infections. The CDC has issued draft recommendations for use of this algorithm in clinical practice, and many hospitals and several EDs have already shown that it can lead to detection of significant numbers of acute HIV infections. Both whole blood and point-of-care versions of the assay exist and have been FDA approved. It is important to recognize that even with these Fourth-Generation assays, there is still a brief window, approximately a 2-week period, where the patient is first infected where antigen may not yet appear in the blood. Viral RNA testing can be done in such instances, but is rarely indicated in the ED.

Emergency physicians should be familiar with the quantitative plasma HIV RNA assay, as it is used routinely for HIV staging and monitoring response to therapy. Test results are reported as copies per milliliter, with survival time directly correlated to viral burden. CD4 lymphocyte count is used to evaluate immunologic status. When this test is unavailable, total lymphocyte count (TLC) count can be used to approximate CD4 count. A TLC $<1{,}000$ cells/μL is highly correlated with a CD4 count of <200 cells/μL.

HIV Testing in the ED

According to the latest 2007 CDC guidelines, HIV testing should be offered at all routine clinical encounters, including the ED. These new guidelines place particular emphasis on the ED as multiple studies have shown the ED to be the most common site within the health care setting for patients with unrecognized HIV. This is felt by many in the public health community to represent a missed opportunity for testing and linkage to care. Proponents of routine testing point to the proven benefits of earlier disease recognition

including slowing the progression of disease, decreasing rates of opportunistic infections, and reduction in the likelihood of disease transmission in the community. Additional direct patient care benefits for HIV testing in the ED are that clinicians' awareness of patients' HIV status can help narrow differential diagnosis (e.g., influenza pneumonia vs. Pneumocystis pneumonia), and improve treatment and disposition decisions.

Fever

All HIV-infected patients who present to the ED with fever need to be thoroughly evaluated. The diagnostic workup for a patient with HIV and a fever is guided by the history, physical examination, and the patient's CD4 count. A person with AIDS is more likely to be infected with atypical organisms than a person with an intact immune system. While this chapter focuses on pathogens that occur almost exclusively in immunocompromised hosts, simultaneous evaluation and treatment for more common organisms is imperative. The initial evaluation of fever in the patient with AIDS should routinely include blood cultures (aerobic, anaerobic, mycobacterial, and fungal), complete blood count, complete metabolic profile, and chest radiograph. Additional testing to consider is summarized in Table 191.2.

TABLE 191.2
Diagnostic Considerations in HIV-Infected Individuals Presenting with Fever

Infectious Symptoms	CD4 Count (cells/mm^3)	Emergency Department Diagnostic Considerations (in Addition to Those for Immunocompetent Patients)
CNS	>250	Serum: RPR or VDRL
		CSF: VDRL and FTA-ABS, culture for bacteria, PCR for HSV/JC, AFB stain, culture for mycobacteria, PCR for *M. tuberculosis*
	<200	Place PPD or obtain interferon gamma release assay
		CSF: culture for fungus, PCR for EBV/VZV, *C. immitis* complement fixation test, *H. capsulatum* Ag
		Serum: C. *immitis* complement fixation test, H. *capsulatum* Ag
		Urine: *H. capsulatum* Ag
	<100	Serum: CMV PCR, *T. gondii* IgG, *C. neoformans* Ag
		CSF: opening pressure, CMV PCR, *C. neoformans* Ag, PCR *T. gondii*, *T. gondii* IgG, India ink stain for *C. neoformans*
Pulmonary	>250	Place PPD or obtain interferon gamma release assay
		Sputum: AFB staining and culture, fungal culture, bacterial culture
		Serum: *H. capsulatum* Ag, *C. immitis* complement fixation test
		Urine: *H. capsulatum* Ag
	<200	Serum: LDH, cryptococcal Ag
		Sputum: induced sputum sent for *P. jiroveci* testing[a]
	<100	Serum: CMV PCR, *C. neoformans* Ag, assay for galactomannan
GI	>250	Serum: Blood cultures (salmonella)
	<200	Stool: assay for *Cryptosporidium parvum*[b], I. *belli*[b], Microsporidia[b]
	<100	Serum: CMV PCR, mycobacterial blood culture for MAC
Generalized	>250	Place PPD or obtain interferon gamma release assay
		Serum: RPR or VDRL
		Urine: urinalysis, bacterial culture
	<200	Serum: *H. capsulatum* Ag, *C. immitis* complement fixation test
		Urine: *H. capsulatum* Ag
	<100	Serum: *C. neoformans* Ag, CMV PCR, mycobacterial blood culture for MAC and TB

Note: For each indication, possible testing is found in the row corresponding to the patient's CD4 cell count *and* all testing for higher CD4 cell counts.

[a]*P. jiroveci* testing of induced sputum depends on the laboratory. Tests can include stains for cysts and trophozoites, such as cresyl violet, Giemsa, Wright, Gram-Weigart or stains for cyst walls, such as Gomori-Methenamine Silver, Gram-Weigart, or toluidine blue. Some laboratories also use immunofluorescent stains (7).

[b]Assays for cryptosporidiosis include acid fast stain, IFA, PCR, EIA, and should be performed only on watery stool. Acid-fast stain of the stool to look for oocysts is the diagnostic test of choice for isosporiasis. Microsporidia are detected using light microscopy with calcofluor-white, Chromotrope 2R, or Uvitex 2B to detect spores (7).

Pulmonary Infections

Pulmonary presentations are among the most frequent reasons for ED visits among patients with known HIV infection (7,10). More than 80% of AIDS patients develop pulmonary disease; *infectious pneumonia,* COPD, tuberculosis (TB), pulmonary hypertension, pulmonary fibrosis, and malignancy involving the lungs are all

increased in patients with HIV (7). The differential diagnosis of infectious pneumonia includes viral, bacterial, mycobacterial, and fungal pneumonias. The more common etiologies are shown in Table 191.3. Although differentiation of these entities in the ED may be difficult, appreciation of the epidemiology and the common findings associated with various pathogens can assist the emergency physician in arriving at a working diagnosis and instituting appropriate treatment and disposition decisions.

TABLE 191.3
Common Causes of Pulmonary Involvement in AIDS

Infection	
Viral	**Protozoa**
Cytomegalovirus	*Pneumocystis carinii*
Herpes simplex virus	*Toxoplasma gondii*
Adenovirus	**Bacteria**
Mycobacteria	*Streptococcus pneumonia*
Mycobacterium tuberculosis	*Haemophilus influenza*
Mycobacterium avium	*Mycoplasma pneumonia*
Mycobacterium kansasii	*Legionella pneumonia*
Fungi	*Staphylococcus aureus*
Histoplasma capsulatum	*Pseudomonas aeruginosa*
Cryptococcus neoformans	*Nocardia*
Coccidioides	*Malignancy*
Candida	**Lymphoma**
Aspergillus fumigatus	*Kaposi sarcoma*
Blastomyces dermatitidis	*Pneumonitis*
	Lymphoid interstitial pneumonitis

The physical examination itself is not likely to aid in establishing a specific diagnosis, but CD4 counts are useful for generating a differential. Patients with CD4 counts >500 cells/mm^3 are most commonly infected with encapsulated bacteria or TB; for those with lower CD4 counts, PCP, fungi, atypical mycobacteria, KS, CMV, and lymphoma are seen with increasing frequency. Patients with fever and productive cough are likely to have a bacterial pneumonia, whereas a nonproductive cough is more likely to accompany PCP,

CMV pneumonia, fungal infection, or neoplasm. Patients with PCP pneumonia often admit to several weeks of symptoms prior to presentation (7). Hemoptysis is most often associated with pneumococcal pneumonia and TB. Fulminant respiratory failure is most likely to be caused by PCP, CMV, or a bacterial etiology.

Evaluation of HIV-infected patients who present with pulmonary complaints should generally include pulse oximetry, chest radiograph, complete blood cell count, arterial blood gas analysis (in the setting of hypoxemia on pulse oximetry), urine Legionella and pneumococcal antigens, sputum culture, and Gram stain. Please refer to Table 191.2 for additional diagnostic considerations. Blood cultures should be obtained in all patients being hospitalized due to the increased risk of bacteremia associated with HIV infection.

KEY TESTING

Pulmonary

- Pulse oximetry
- CXR
- CBC
- ABG if hypoxemia on pulse oximetry
- Blood cultures for hospitalized patients

Radiographic patterns are suggestive of certain disorders but are usually not diagnostic. A focal infiltrate often suggests bacterial pneumonia, whereas a diffuse interstitial or perihilar reticular or ground glass appearance is associated with PCP or CMV. Cysts, blebs, nodules, and pneumothoraces are common with PCP (usually with CD4 <100 cells/mm^3), but negative CXRs have been reported in up to 20% of patients (7) as well. A pneumothorax in an AIDS patient should be presumed to be PCP until proven otherwise. Pleural effusions are commonly seen in AIDS patients. Most effusions are due to bacterial infections, but they can also be seen with PCP, fungal, and parasitic infections. Hilar adenopathy with diffuse pulmonary infiltrates can suggest cryptococcosis, histoplasmosis, mycobacterial infection, or neoplasm. KS can present with cough, fever, and dyspnea and may mimic PCP on chest radiograph, or may present

with effusions. In contrast to KS, lymphoma can present with well-defined large and peripheral nodules. Computed tomography (CT) scan is highly sensitive for a variety of entities (7), and bronchoscopy should also be considered.

Bacterial Agents

In HIV-infected patients, the most common bacterial pulmonary infections are with *Streptococcus pneumoniae, Haemophilus influenzae, Pseudomonas aeruginosa,* and *Staphylococus aureus.* Infections with *Mycoplasma pneumoniae, Chlamydia pneumoniae,* and Legionella are relatively less common. Pneumococcal vaccination is an indicated prophylactic intervention for all HIV patients because the risk of pneumococcal bacteremia increases 150- to 300-fold in the setting of HIV infection (7). *P. aeruginosa* is more commonly seen in the setting of AIDS. Treatment of pneumonia should follow standard recommendations (11). Uncomplicated patients can be treated with a macrolide or doxycycline alone, while significant immunocompromise or a plan to hospitalize indicates treatment with a β-lactam or ertapenem plus a macrolide. Patients requiring ICU admission should receive therapy with antipseudomonal activity and potentially be treated with vancomycin or linezolid as well. If PCP is a possibility, trimethoprim/sulfamethoxazole (TMP/SMX) should be *added* to conventional therapy, as described below. In patients with risk factors for TB, treatment with fluoroquinolones should be avoided because it may lead to inadvertent partial treatment of a TB infection and consequent delays in appropriate therapy (11).

Fungal Pneumonias

P. jiroveci (PCP) is one of the most common opportunistic infections and a leading cause of mortality in AIDS. PCP infections typically occur in adults with CD4 counts <200 cells/mm^3. The typical complaint is an insidious, nonproductive cough, dyspnea with exertion, unexplained fever, chest pain, and fatigue developing over days to weeks. Chest CT has a much higher sensitivity for detecting PCP than CXR and will typically show a ground glass appearance;

however, a negative CT does not rule out the disease (7). Arterial blood gas analysis for an increased alveolar–arterial (A–a) oxygen gradient is indicated if there is a suspicion for hypoxemia. LDH is elevated in 90% of PCP pneumonia patients. However, the specificity of LDH is relatively low (4) and it should not be used for diagnosis.

In the ED, a presumptive diagnosis of PCP is made if there is unexplained hypoxia. PCP cannot be grown in the laboratory, and diagnosis is made by indirect immunofluorescent staining using monoclonal antibodies, or a variety of stains. Expectorated sputum is not helpful, but induced sputum has a sensitivity of 56%. Bronchoscopy with bronchoalveolar lavage (BAL), brush biopsy, or transbronchial biopsy is often required, as it has a sensitivity of 95%.

When PCP is suspected in the ED, treatment should be initiated without waiting to obtain a definitive diagnosis. Patients able to take PO therapy can be given two Bactrim DS every 8 hours. IV therapy is TMP/SMX 20/100 mg/kg/d in three divided doses. The duration of TMP/SMX should be 21 days. Systemic corticosteroid treatment, administered as prednisone 40 mg PO bid or methylprednisolone 30 mg IV bid, results in a 50% reduction in mortality for patients with a PaO_2 <70 mm Hg or an A–a oxygen gradient of >35 mm Hg (12). Prednisone should be tapered over 3 weeks. All patients requiring steroids should be admitted to the hospital. Patients being discharged who may have PCP pneumonia require reliable follow-up, as mortality for untreated PCP is 100%. Prophylactic therapy for PCP is recommended with one Bactrim DS PO daily to prevent reinfection and in all patients with CD4 cell counts <200 cells/mm^3.

The mortality for PCP in the setting of respiratory failure is close to 60%. Patients requiring ventilatory support should be maintained on low tidal volumes and plateau pressures with a high index of suspicion for developing pneumothorax. Asymptomatic patients with a small pneumothorax ($<20\%$) may be safely treated with observation or insertion of a Heimlich valve (13).

Histoplasma capsulatum is a fungal infection that can cause respiratory disease in immunocompetent patients and disseminated disease in patients with a CD4 <150 cells/mm^3. It is endemic to the central and southeastern United States, and clinical disease occurs in

5% to 27% of at-risk AIDS patients. The organism grows in soil and is found in bat and bird droppings. Infection with *H. capsulatum* can also affect the bone marrow, GI tract, and CNS and can present with symptoms of malaise, fever, weight loss, meningitis, diarrhea, or cough. It can be detected by culture and by staining of affected tissue or peripheral blood; however, antigen detection in urine, blood, or BAL fluid is also useful. In disseminated disease, urine and serum antigen have sensitivities of 95% and 85% respectively (7). Treatment is liposomal amphotericin B 4 mg/kg IV qd in severe disease or itraconazole 200 mg PO tid for 3 days followed by bid treatment for 1 year in less severe disease (7).

Blastomyces dermatitidis is endemic to the South Central and Midwestern United States. Clinical infection is rare but has a high mortality rate in AIDS patients. Most patients present with fevers, weight loss, and cough and have an abnormal CXR. Diagnosis is by staining and culture of sputum, tissue biopsy, BAL, or CSF culture. Treatment is with amphotericin B.

Aspergillus infection can present as either pulmonary or disseminated disease in AIDS patients. The pulmonary form is characterized by cough, fever, hemoptysis, and dyspnea. A cavitary upper lobe lesion or alveolar or bilateral infiltrates may be seen on chest radiography. It may also cause tracheobronchitis with stridor and wheezing. The disseminated form can present with osteomyelitis, meningoencephalitis, sinusitis, or skin and soft tissue infection. Diagnosis is by tissue biopsy, BAL stain, or culture. Voriconazole is the preferred treatment, but due to interaction with NNRTIs and PIs, amphotericin B 4 mg/kg/d IV is an acceptable alternative (7).

C. neoformans, a ubiquitous fungal pathogen, can cause pulmonary disease in AIDS patients resulting in cough, dyspnea, pleuritic chest pain, fever, and malaise potentially progressing to acute respiratory distress syndrome. Radiograph findings are nonspecific and include consolidation and reticulonodular infiltrates. Serum cryptococcal antigen is the diagnostic test of choice. Treatment is discussed later in this chapter.

Coccidioides immitis is endemic in the southwestern United States. It causes pneumonia in immunocompetent patients, but dissemination occurs in those with a CD4 count $<250/mm^3$ and can include skin, CNS, and GI manifestations. CXR findings are usually abnormal but nonspecific. Diagnosis is made by culture, serology, or histopathology. Fluconazole 400 mg PO qd is used for focal pneumonia, and amphotericin B 5 mg/kg/d IV is used for diffuse pneumonia and nonmeningeal disseminated disease. Fluconazole 1000 mg IV qd is used for meningitis (7).

Tuberculosis

Mycobacterium tuberculosis is one of the leading causes of death in AIDS patients worldwide. The incidence of TB in the AIDS population is estimated to be 50 to 200 times that of the general population (14) due to increased reactivation of latent infections, high attack rates, and rapid progression to clinically significant disease. Pulmonary TB is usually the initial finding in HIV-infected patients with CD4 counts of 200 to 500 cells/mm^3.

Classic presenting symptoms of TB include cough (with hemoptysis), fever, night sweats, and weight loss. However, in patients with advanced immunosuppression clinical manifestations are atypical, and extrapulmonary findings are more common. Frequent sites and manifestations of disseminated disease include peripheral lymph nodes, pleuritis, pericarditis, meningitis, bone marrow, and the GI and genitourinary systems. Classic radiographic findings in immunocompetent individuals include upper lobe lesions with cavitation, pleural effusions, mediastinal adenopathy and alveolar opacities. In patients with CD4 counts <50 cells/mm^3, atypical radiographic features are seen with increased frequency.

ED physicians should maintain a high index of suspicion for TB among HIV-infected patients with pulmonary symptoms. All patients in whom TB is being considered need to be admitted to the hospital in respiratory isolation until the disease is ruled out. The diagnosis of TB by AFB staining and culture of the sputum is difficult as the sensitivity of the AFB smear is only about 50% and not improved with induced sputum or bronchoscopy. Nucleic acid amplification is

more sensitive than an AFB smear and can be done if there is a positive AFB smear or a negative smear and a high clinical suspicion. In miliary TB, blood cultures are positive about 50% to 60% of the time, whereas the sputum culture is positive in only 25% of cases. About one-fourth of HIV-infected patients with active TB will have a false-negative result with PPD testing and interferon gamma release assays (7).

HIV patients with TB should receive four-drug initial therapy with isoniazid, rifampin, pyrazinamide, and ethambutol (11). All HIV-infected patients with a positive PPD (> 5 mm of induration) or interferon gamma release assay or chest x-ray consistent with TB (regardless of screening test results) should be asked about a history of treatment. If they have not been adequately treated, they should receive prophylaxis (chest x-ray abnormalities require exclusion of active TB) with isoniazid 300 mg plus pyridoxine 50 mg PO qd for 9 months (11).

Neurologic Involvement

CNS disease occurs in about 90% of patients with AIDS. A wide variety of neurologic symptoms are seen in patients with HIV, including altered mental status, coma, seizures, headache, and focal neurologic symptoms. Common infectious complications in patients with access to effective ART include progressive multifocal leukoencephalopathy (PML), cerebral toxoplasmosis, and cryptococcal meningitis. CMV ventriculoencephalitis and primary CNS lymphoma are less common. Occasionally, neurosyphilis and tuberculous meningitis are seen as well. Noninfectious complications can include HIV-associated neurocognitive deficits, peripheral neuropathies, metabolic encephalopathy, lymphoma (primary and secondary), and KS. In addition, secondary complications of neurologic disease can cause a presentation with embolic or ischemic stroke, subarachnoid hemorrhage, obstructive hydrocephalus, and Immune reconstitution inflammatory syndrome (IRIS).

Evaluation of HIV-positive patients with altered mental status or headache should proceed as in the non-HIV–infected population. Signs of impending herniation should prompt emergent treatment,

neuroimaging, and neurosurgical consultation. Otherwise, neuroimaging and lumbar puncture (LP) should be obtained in cases of altered mental status or headache in which another cause is not clearly identified or with a clear other indication for workup (i.e., worst headache of life, focal neurologic deficit) (15). For patients with CD4 cell counts <200 cells/mm^3 and/or focal deficits or new seizures, neuroimaging should always proceed LP (16). For patients with CD4 cell counts >200 cells/mm^3 who present with fever and meningismus (in the absence of focal neurologic deficits), immediate LP may be performed. A proposed algorithm for the diagnosis and empiric treatment of HIV patients with suspected CNS disease is presented in Figure 191.1 (17).

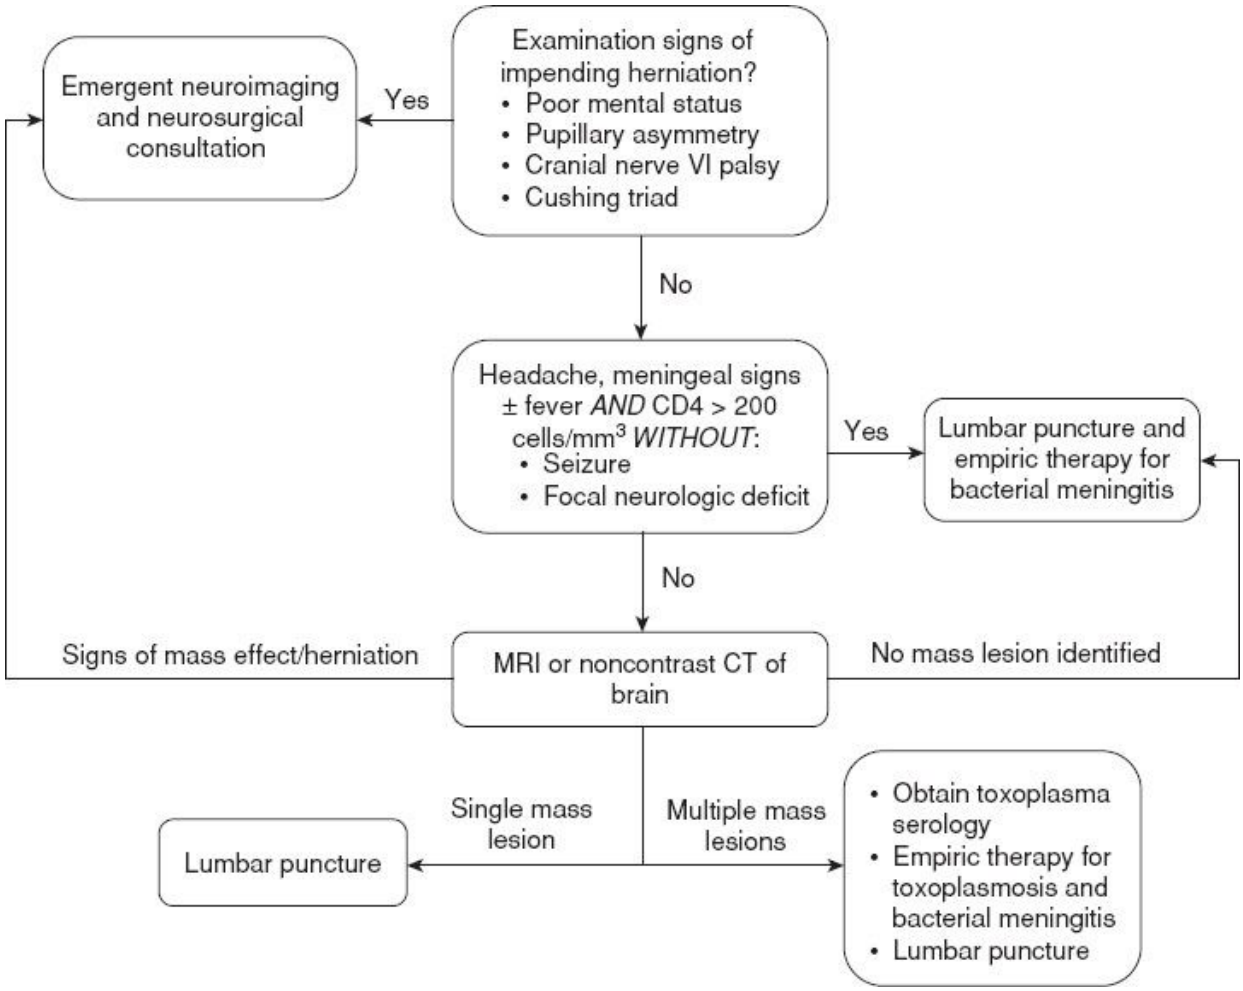

FIGURE 191.1 Algorithm for initial work-up and empiric treatment for patients with HIV and altered mental status. Note that lumbar

puncture should not be performed if there is evidence of mass effect on imaging. (Adapted from Tan IL, Smith BR, von Geldern G, et al. HIV-associated opportunistic infections of the CNS. *Lancet Neurol.* 2012;11:605–617.)

KEY TESTING

Neurologic

- Neuroimaging (CT or MRI)
- LP

Specific CSF studies should include measurement of opening pressure, cell count, glucose, protein, Gram stain, bacterial, fungal, and mycobacterial cultures. Additional testing to consider is detailed in Table 191.2; however, asking the laboratory to retain excess CSF is always prudent. Additional diagnostic considerations include serum *Toxoplasma gondii* IgG levels, chest imaging, and interferon gamma release assay looking for evidence of TB (17).

If the entire ED workup is unrevealing and the patient has significant signs or symptoms, more advanced diagnostic evaluation should be pursued immediately, preferably in the inpatient setting. In addition, all patients with new or changing CNS lesions should be considered for hospital admission.

T. gondii is the most common cause of focal intracranial mass lesions in patients with HIV infection (2% to 4%). Affected patients have CD4 counts of <100 cell/mm^3 and present with fever, headache, and confusion evolving over 1 to 2 weeks. Seizures can occur, and 80% will have focal neurologic deficits. Serum antibiodies to *T. gondii* are highly sensitive for CNS toxoplasmosis in the setting of focal lesions of the brain parenchyma (17). In this way, presumptive diagnosis can be made by the presence of multiple subcortical lesions that show ring enhancement on CT or magnetic resonance imaging (MRI). However, radiographic and clinical features are similar to a wide variety of other CNS disorders (lymphoma, cerebral TB, cryptococcosis, bacterial abscess, and rarely, PML), and definitive diagnosis may require biopsy. Patients

with suspected toxoplasmosis should be admitted and treated empirically with pyrimethamine 200 mg PO × 1, then 50 mg (<60 kg) to 75 mg (>60 kg) PO daily plus sulfadiazine 1,000 mg (<60 kg) to 1,500 mg (>60 kg) PO q6h plus leucovorin 25 mg PO qd (7). Dexamethasone, 4 mg IV, may be used in cases with mass effect causing clinical deterioration. Seizure prophylaxis is not recommended. Bactrim is indicated for chronic suppressive therapy after initial treatment and for prophylaxis for those with a positive serology and a CD4 cell count <100 cells/mm^3.

C. neoformans is a fungus that occurs in up to 10% of AIDS patients, usually with CD4 cell count <100 cells/mm^3. CNS involvement presents with subacute onset of headache, fever, and malaise. Characteristically, meningismus may be absent, and focal neurologic deficits are less common. CSF cryptococcal antigen tests are nearly 100% sensitive and specific, while India ink staining is 60% to 80% sensitive. *C. neoformans* can also cause disseminated disease, and all patients with a positive serum cryptococcal antigen test should undergo an LP regardless of neurologic symptoms (7). Communicating hydrocephalus is responsible for 90% of deaths associated with CNS cryptococcosis. In patients with symptoms suggestive of elevated ICP or opening pressure >25 cm H_2O, CSF should be drained until the pressure falls by 50% or to <20 cm H_2O (17). Cryptococcosis is treated with amphotericin B 0.7 mg/kg/d IV plus flucytosine 25 mg/kg PO qid for 2 weeks and then fluconazole for 8 weeks (7). Suppressive therapy is often continued after successful treatment.

JC virus is present and asymptomatic in most healthy people. In patients with HIV who are immunocompromised, JC virus infection of the brain parenchyma results in PML. Although most cases occur with CD4 cell count <100 cells/mm^3, it may occur at higher CD4 counts. PML commonly presents with multifocal neurologic deficits resulting from demyelinating white matter lesions, and it usually develops over a period of weeks to months. Patients are typically afebrile and do not necessarily complain of pain. Acute presentation causing seizures or mimicking stroke is occasionally seen. CT or MRI shows lesions of subcortical white matter, and the diagnosis is

generally made with PCR (80% sensitivity, 90% to 99% specificity) or brain biopsy. Mean survival is 6 to 9 months, which can be prolonged only through effective immune reconstitution with ART.

CMV occurs in patients with CD4 <50 cells/mm^3 and can cause ventriculoencephalitis, ascending polyradiculomyelopathy, and retinitis. CMV encephalitis will present with headache, fever, and delirium. Ataxia, cranial neuropathy, and nystagmus can be prominent features. PCR or culture of CSF or blood can be used for diagnosis. Patients will frequently have concurrent retinitis, and an ophthalmology evaluation to consider intravitreal ganciclovir is indicated for patients with CMV encephalitis. Treatment for CMV encephalitis is ganciclovir 5 mg/kg IV bid plus foscarnet 90 mg/kg IV bid (7).

CNS lymphoma is usually seen in patients with CD4 <50 cells/mm^3. Patients complain of headache, focal neurologic deficits, or neuropsychiatric symptoms, and lack of fever is characteristic. Seizures frequently occur, and patients can present with symptoms of increased ICP. Imaging more commonly shows a single periventricular or periependymal lesion, and CSF PCR for EBV is 50% to 80% sensitive and >90% specific. Nonetheless, patients are often treated empirically for toxoplasmosis, and definitive diagnosis may require biopsy. The prognosis is poor with median survival of <1 month. Whole-brain irradiation, steroids, and chemotherapy may extend life expectancy to several months.

Treponema pallidum causes neurosyphilis and should be considered in the differential of any HIV-positive patient with meningeal signs, dementia, memory loss, iritis, uveitis, optic neuritis, or new focal neurologic findings. CSF usually shows a mononuclear pleocytosis (>10 WBC/mL). FTA-ABS testing of the CSF is sensitive for neurosyphilis, and can be used as a screen for neurologic involvement (7). VDRL and RPR in the CSF are specific but not sensitive, thus both CSF-VDRL and FTA-ABS should be performed. Patients with neurosyphilis should be treated with aqueous penicillin G 4 million IU IV q4h for 14 days.

HIV-associated neurocognitive deficits are a spectrum of cognitive abnormalities present to some extent in 50% of HIV-positive patients.

Abnormalities can include memory impairment, apathy, cognitive slowing, difficulties with attention and concentration, depression, social withdrawal, incoordination, and ataxia. Physical findings include clonus, frontal release signs, hyperactive deep-tendon reflexes, and (often) hallmarks of advanced AIDS. It is important to recognize that AIDS dementia is a diagnosis of exclusion and is usually confirmed on the basis of neuropsychological testing after brain MRI and LP. The appearance of new signs or symptoms should prompt a workup for treatable CNS processes. HIV-associated neurocognitive decline is slowed by ART.

Peripheral Nervous System

HIV is associated with increased risk for a variety of *inflammatory demyelinating polyneuropathies*. Early in HIV infection, acute demyelinating neuropathies are seen (acute inflammatory demyelinating polyneuropathy [AIDP], Guillain–Barré syndrome); later on, chronic relapsing motor weaknesses are more common (chronic inflammatory demyelinating polyneuropathy [CIDP]). Presentation is typically an ascending paralysis with mild sensory complaints. CSF studies reveal elevated protein levels and a mononuclear pleocytosis. AIDP is treated with plasmapheresis and IVIG, whereas CIDP is treated with prednisone, plasmapheresis, or IVIG.

HIV-associated neuromuscular weakness syndrome is thought to be caused by a reaction to nucleoside analog reverse transcriptase inhibitors (NRTIs). Typical presentation includes acute or subacute new-onset limb weakness, areflexia, ascending paresis, and possible sensory involvement in association with an elevated CPK and lactate. Other conditions such as Guillain–Barré, myasthenia gravis, hypokalemia, stroke, or myelopathy should be ruled out. Stopping the offending medication is usually effective.

Other diseases that can cause peripheral neuropathies include antiretroviral toxic neuropathy, distal sensory neuropathy, tarsal tunnel syndrome, polyradiculitis, vacuolar myelopathy, diabetes, B_{12} deficiency, neurotoxic drugs, alcoholism, and mononeuritis.

Symptoms can be treated with pain-modifying agents such as gabapentin, tricyclic antidepressants, or phenytoin. Ibuprofen is also a reasonable first-line agent with referral to an HIV specialist or neurologist for nerve conduction testing and possible biopsy.

Gastrointestinal Involvement

AIDS-related complications can involve the entire length of the GI tract. Causes of abdominal pain in HIV patients can include intestinal perforation (from CMV, KS, or lymphoma), obstruction or intussusception (from lymphoma or infection), peritonitis and ascites (from histoplasmosis, TB, mycobacterium avium complex (MAC), toxoplasmosis, cryptococcus, or lymphoma), gastritis, and biliary disease. Treatment in the ED should focus on ruling out life threats, supportive care, and obtaining appropriate studies for further investigation.

KEY TESTING

Gastrointesintal

- CBC
- Electrolytes/BUN/creatinine
- Liver function tests
- Stool culture and parasites for diarrhea

Oropharynx

Oral candidiasis is the most common oral manifestation of HIV infection and affects more than 80% of AIDS patients. *Candida albicans* typically involves the tongue and buccal mucosa. It can be distinguished from hairy leukoplakia by its characteristic whitish, lacy plaques, which are easily scraped away from an erythematous base. Microscopic examination of the material by potassium hydroxide smear can confirm the diagnosis in the ED. Fluconazole 100 mg po qd × 14 days is one of the most effective treatments, and posaconazole is used for refractory cases. For all candidal infections in HIV patients, immune reconstitution is an important part of treatment.

Hairy leukoplakia, thought to be caused by the EBV, results in a benign epithelial thickening and typically involves the lateral borders of the tongue causing it to have hair-like projections. In contradistinction to candidal plaques, hairy leukoplakia cannot be easily scraped off. Painful oral and perioral ulcerations may be caused by *herpes simplex virus* (HSV) and can be diagnosed in the ED by the identification of multinucleated giant cells in scrapings of the lesions. Oral HSV should be treated with acyclovir 400 mg PO TID for 10 days. *Aphthous ulcers* are small crateriform ulcers with white to yellow membranes surrounded by an erythematous ulcer. The etiology of aphthous ulcers is unclear. ED treatment of oral ulcers can include lidocaine solution or topical steroids mixed with a topic anesthetic such as Orabase. Patients with oral lesions should be referred to their HIV specialist for potential biopsy, as they are at higher risk for oropharyngeal squamous cell carcinoma and oral involvement with KS.

Esophagus

Esophagitis can present with odynophagia, dysphagia, or chest pain. A CD4 count >200 cells/mm^3 suggests non-HIV–related causes of esophagitis. In patients with CD4 <200 cells/mm^3, candida is responsible for esophagitis in 50% to 70% of cases. Other common causes are HSV, CMV, and aphthous ulcers. The most cost-effective approach to managing patients with esophageal complaints is to initiate empiric therapy for presumptive candidiasis with fluconazole 400 mg PO daily for 3 weeks, which is often curative (11). Refractory cases will then require endoscopy, biopsy, and cultures. Consider admission and empiric IV antifungal agents for those who are refractory or have poor tolerance of liquids and oral medications.

Liver and Biliary Tract

Hepatobiliary complaints can be caused by a wide range of conditions. Hepatitis B virus (HBV) and hepatitis C virus (HCV) coinfection in HIV patients is a complex topic. In addition to traditional concerns with hepatitis viruses, emergency physicians

may encounter acute liver disease from hepatitis B flares related to changes in ART. Hepatic steatosis is also prevalent in HIV patients due to coinfection with HCV, antiretroviral therapies, or more traditional risk factors. Opportunistic organisms associated with hepatitis include CMV, MAC, *M. tuberculosis,* and *H. capsulatum.* In addition, AIDS patients can get cholangiopathy that is commonly caused by cryptosporidium. Patients typically present with right upper quadrant pain with elevated liver enzymes, alkaline phosphatase, and total bilirubin. The initial diagnostic test should be a right upper quadrant ultrasound, and ERCP is often necessary for diagnosis of cholangiopathy. In addition, alcoholism, drug-related liver injury or hypersensitivity (see "ART"), and liver involvement with IRIS are other causes of hepatitis in HIV patients.

Anorectal Disease

Proctitis is characterized by painful defecation, rectal discharge, and tenesmus and can be caused by *Neisseria gonorrhoeae, Chlamydia trachomatis,* syphilis, lymphogranuloma venereum, and HSV. Proctocolitis presents with the same symptoms as proctitis but is accompanied by diarrhea. Typical causative organisms include those just listed plus bacterial agents such as *Shigella, Salmonella, Campylobacter,* and *Entamoeba histolytica.* Diagnostic evaluation in the ED should include anoscopy with evaluation of stool for blood, leukocytes, ova and parasites, bacterial cultures, *N. gonorrhoeae,* and *C. trachomatis;* HSV culture or Tzanck prep; and RPR.

Diarrhea

Diarrhea is a problem in 50% to 90% of AIDS patients, may be chronic or acute, and may vary in severity from multiple loose stools per day to massive fluid loss with prostration, fever, chills, and weight loss. ED evaluation should be directed toward stabilization, hydration, and obtaining appropriate diagnostic studies. Table 191.2 presents diagnostic considerations based on CD4 cell count. In one large study, the most common bacterial causes of acute diarrhea were *Clostridium difficile* followed by Shigella, *Campylobacter jejuni,*

Salmonella, *S. aureus,* and MAC (18). For HIV patients who present with acute diarrhea, the ED physician should consider ordering blood cultures due to the much higher concern for bacteremia (particularly with Salmonella). Most patients with a CD4 cell count >200 cells/mm^3 will improve with conservative therapy, and therefore these patients can be managed similar to non-HIV–infected patients with acute diarrhea. As the CD4 cell count drops below 200 cells/mm^3, Cryptosporidia, Microsporidia, Isospora, and bacteria cause more persistent infection and may require diagnosis and treatment. In patients with CD4 cell count <50 cells/mm^3 CMV may cause colitis, and disseminated MAC may cause severe disease—stool examination for CMV and mycobacteria is not necessary and can be misleading. For those with severe symptoms, CT scanning should be considered to look for pseudomembranous colitis, CMV colitis, lymphoma, and mechanical complications. Noninfectious causes to consider include irritable bowel syndrome, medication side effects (particularly nelfinavir and ritonavir), dietary change, lactic acidosis, and inflammatory bowel disease. Even after workup, about 25% to 40% of HIV patients with acute diarrhea will not have an identifiable cause.

The differential diagnosis of chronic diarrhea in an HIV-infected patient includes antiretroviral medication-associated diarrhea, HIV enteropathy, HIV-associated autonomic neuropathy, chronic pancreatitis-associated malabsorption, chronic infections with organisms mentioned earlier in this section, and malignancies such as KS and lymphoma. *E. histolytica, Giardia lamblia, Isospora belli,* Microsporidia, and MAC are more commonly seen in AIDS patients with chronic diarrhea. ED testing is the same as for acute diarrhea. Ultimately, endoscopy may be necessary to diagnose CMV colitis, mycobacterial or parasitic enteritis, or malignancy-associated diarrhea. 25% of AIDS patients with chronic diarrhea will have no pathogen detected after extensive evaluation.

Table 191.4 presents treatment options for diarrhea in HIV-positive patients. Potential indications for admission of the HIV-infected patient with diarrhea include concern for salmonella bacteremia, CD4 count <200 cells/mm^3, severe symptoms with

dehydration/electrolyte imbalance and acidosis, and chronic diarrhea with advanced malnutrition. In general, patients who can tolerate oral intake and are hemodynamically stable can be discharged from the ED with outpatient follow-up. Patients with nonbloody diarrhea without systemic symptoms can be treated with antimotility agents (loperamide, diphenoxylate, tincture of opium, octreotide, etc.) if needed. If bacterial infection is strongly suspected, the patient can be treated with ciprofloxacin 500 mg PO bid × 5 days, and metronidazole 750 mg PO tid can be given for 7 days if parasitic infection is suspected. As with most HIV-related conditions, immune reconstitution is necessary to control persistent diarrhea.

TABLE 191.4
Selected Pathogens that Cause Diarrhea in HIV-Positive Patients

Pathogen	Clinical Features	Treatment	Comment
C. difficile	Watery diarrhea Fecal leukocytes Recent antibiotic use	Flagyl 500 mg PO TID for 10–14 d	Imodium and lomotil are contraindicated
CMV colitis	Fever Abdominal pain, diarrhea Weight loss CD4 count <50 cells/mm^3	Antivirals: valganciclovir, ganciclovir, or foscarnet	Diagnosis via endoscopy and biopsy Major complications: perforation and hemorrhage
Cryptosporidium parvum	Fever Nausea Vomiting Abdominal Cramps	*ART for immune reconstitution* (only reliably effective therapy) Nitazoxanide 1 g po bid × 60 d	Diagnosis via acid-fast staining of stool specimens, monoclonal antibody, or ELISA
Entamoeba histolytica	Dysentery Liver abscesses	Flagyl 500 mg PO TID for 7–10 d	Parasite transmitted via the fecal–oral route Diagnosis via ova and parasite (O & P) examination of the stool
Isospora belli	Watery nonbloody diarrhea Abdominal pain Fever Vomiting Weight loss	Immune reconstitution with ART TMP-SMX DS 1 tab Q12 for 10 days	Parasite transmitted via the fecal–oral route Diagnosis via ova and parasite (O & P) examination of the stool
Mycobacterium avium complex (MAC)	Diarrhea Fever Night sweats Cough Weight loss	Clarithromycin 500 mg q12h plus ethambutol 15 mg/kg/d PO Prophylaxis when CD4 <50 cells/mm^3: Azithromycin 1,200 mg PO weekly	Disseminated disease occurs with CD4 counts <100/mm^3 ELISA, ART

Malignancies

HIV patients with low CD4 counts are at increased risk for several malignancies including KS, non-Hodgkin lymphoma, lung cancer, lymphoblastic lymphoma, CNS lymphoma, and cervical and anal cancer associated with human papillomavirus (HPV). Patients with suspected anal cancer should be referred for biopsy.

Most HIV-associated lymphomas are B-cell lymphomas, and their incidence increases with lower CD4 cell levels. Non-Hodgkin lymphoma is caused by EBV and is seen most frequently in those with CD4 count <100 cells/mm^3. Patients with lymphoma usually present to the ED with fevers and lymphadenopathy and, depending on the state of disease, a variety of other findings including liver dysfunction, abnormal blood cells, and pulmonary, GI, or CNS complaints. CT scan and biopsy will often suggest the diagnosis.

Dermatologic Involvement

Cutaneous manifestations of AIDS likely to be seen in the ED include neoplasms, drug rashes, dermatitis, HSV, herpes zoster, and molluscum contagiosum. In addition, HIV patients are at an increased risk of bacterial skin infections and bacteremia.

KS is one of the most common HIV-associated malignancies. It occurs mostly in men who have sex with men and is caused by human herpes virus-8 (HHV-8). Lesions are typically firm, purple to black in color, and can be macules, patches, nodules, or papules. Frequent locations are the trunk, face, legs, oral cavity, or genitalia. Complications include lymphedema and visceral involvement. Patients with suspected KS need prompt referral for biopsy. The disease is not curable, and treatment goals are palliative.

HSV is common in AIDS patients and can present as either a localized infection or systemic disease. Localized infections respond well to standard therapy with oral valacyclovir 1 gm PO bid for 14 days. IV therapy with acyclovir 5 mg/kg q8h is required in cases of severe or disseminated infection. Suppressive therapy with valacyclovir 500 mg PO bid is effective in decreasing rates of recurrence (7).

Reactivation of varicella zoster virus is 17 times more likely in patients with HIV than the general population. The clinical course is prolonged, and multidermatomal involvement is common. Outpatient treatment is acceptable for those with single dermatomal involvement who are not significantly immunosuppressed. Regimens include valacyclovir 1 gm PO tid for 10 days in single dermatomal cases and acyclovir 15 mg/kg IV q8h with severe visceral or

cutaneous disease. Admission to an isolation bed is indicated for those with severe multidermatomal zoster, disseminated disease, or ophthalmic zoster (19).

S. aureus, increasingly MRSA, is the most common cause of skin and soft tissue infection in those with HIV. Cutaneous abscesses should be lanced and drained in the ED. Owing to the high risk of bacteremia in HIV-positive patients with skin and soft tissue infections, clinicians should consider lowering their threshold for brief observation or admission for IV antibiotics, particularly in those with low CD4 cell counts, severe cellulitis, and/or fever.

Bacillary angiomatosis is a vascular skin infection most commonly caused by the gram-negative rods *Bartonella henselae* (associated with cats and fleas) and *Bartonella quintana* (associated with the human body louse) in those with CD4 counts <50 cells/mm^3. Lesions range from few to hundreds and are usually red to purple and papular, pedunculated, nodular, or verrucous. Differential includes KS, hemangioma, pyogenic granuloma, dermatofibroma, and cherry angioma. Referral for biopsy is critical, as the infection can disseminate to nearly any organ system. Diagnosis can be made by serology, PCR, or silver staining of tissue specimens. First-line therapy is erythromycin, and relapses are common.

Disseminated C. *neoformans* disease can present with dermal involvement manifesting as nodular, follicular, papular, or ulcerative skin lesions that may resemble molluscum contagiosum. If suspicion for cryptococcus exists, a serum cryptococcus antigen test should be performed, and an LP should be obtained following any positive serum test. Referral for biopsy and culture of the rash is also indicated. Treatment for cutaneous cryptococcus (with a negative LP) is fluconazole, 400 mg/d for 8 weeks, then 200 mg/d.

Other cutaneous manifestations seen frequently in HIV patients include drug eruptions, scabies, papular pruritic eruption (darkened papules on extremities), prurigo nodularis (symmetric lesions on arms and trunk involving lichenification and treated with antipruritic agents and steroids), *N. gonorrhea,* and syphilis.

Ophthalmologic Manifestations

Although a wide range of ophthalmic diseases can occur in patients with AIDS, recognition of two processes is critical for the emergency physician.

CMV retinitis is the most serious ocular opportunistic infection and the leading cause of blindness in patients with AIDS. With advances in ART, the prevalence of CMV retinitis is declining, but patients who discontinue ART may experience symptoms (20). Presenting complaints are variable and may include blurred vision, changes in visual acuity, floaters, flashes of light, photophobia, eye redness, or pain. Diagnosis is based on fundoscopic examination, which usually shows fluffy yellow-white perivascular lesions with areas of hemorrhage. These findings may be easily confused with retinal cotton wool spots, a benign lesion with no prognostic significance. Because of the risk of blindness associated with CMV retinitis, suspicion for the disease requires *immediate* ophthalmologic consultation. Treatment regimen can consist of intraocular ganciclovir implants with oral valganciclovir for vision-threatening lesions or oral valganciclovir alone for lesions on the periphery of the retina. Intravitreous injection of ganciclovir may be given at the time of diagnosis if there is a delay of implant insertion.

Herpes zoster ophthalmicus is another common cause of ocular damage in patients with HIV. The typical presentation is pain or paresthesia in the distribution of cranial nerve V_1, followed by the emergence of the vesicular zoster skin rash. Complications may include conjunctivitis, episcleritis, iritis, and more concerningly, keratitis, secondary glaucoma, and retinitis. All patients with suspected zoster ophthalmicus require immediate ophthalmology consultation. Treatment involves acyclovir 30 mg/kg/d IV for 14 days followed by ganciclovir 1 g PO tid for acute retinal necrosis, or IV ganciclovir 5 mg/kg twice daily, foscarnet 90 mg/kg twice daily, and intravitreal ganciclovir for progressive outer retinal necrosis.

Other ophthalmic complications that occur with low CD4 count include microangiopathy (intraretinal hemorrhages and cotton wool spots; no treatment required), PCP choroidopathy (orange or yellow lesions at posterior pole of retina; treated as with pulmonary PCP), toxoplasmosis retinitis (multiple whitish retinal lesions without

hemorrhage; treated as with CNS toxoplasmosis), and syphilis (uveitis, optic neuritis, chorioretinitis; treated with penicillin G 4 million units IV q4h for 14 days) (7).

Hematology

Chronic anemia in AIDS is characterized by a normocytic, normochromic anemia with a low reticulocyte count and low erythropoietin (EPO) level. ART usually results in improvement. HIV-related infections or malignancies can also be associated with sudden worsening of anemia. Nutritional deficiencies including B_{12} and folate can result in megaloblastic anemia, low reticulocyte count, low serum B_{12}, and low serum folate. HIV medications causing anemia include AZT, TMP-SMX, phenytoin, ribavirin, pyrimethamine, and ganciclovir. Other drugs such as dapsone, primaquine, and ribavirin can cause a hemolytic anemia. HIV-infected patients are also at risk for idiopathic thrombocytopenia, neutropenia, and thrombotic thrombocytopenia purpura (7).

Antiretroviral Therapy

In 1996, with advancing dissemination of ART, the CDC reported a decline in the number of AIDS-related deaths for the first time. Although not commonly instituted in the ED, ART is an important aspect of management in HIV-infected patients, and emergency physicians should have a basic understanding of the classes of drugs available, adverse drug reactions likely to be seen, and the current guidelines for initiating treatment.

There are several classes of antiretroviral drugs including the NRTIs, NNRTIs, PIs, an entry inhibitor, a fusion inhibitor, and an integrase inhibitor. Each group of drugs independently interrupts the normal life cycle of HIV.

The first drug demonstrated to have antiretroviral activity, Zidovudine or AZT, belongs to the NRTIs, which are competitive inhibitors of the viral enzyme reverse transcriptase. Side effects of NRTIs that are relevant to emergency physicians include distal sensory peripheral neuropathy with didanosine (ddI), stavudine

(d4T), and zalcitabine (ddC); pancreatitis with ddI; acute hepatitis (sometimes resulting in fatal hepatic necrosis) caused by hypersensitivity to abacavir (ABC); and hepatitis B flares resulting from institution (due to IRIS) or discontinuation of an NRTI.

NRTI-related mitochondrial toxicity can cause life-threatening lactic acidosis, usually due to ddI, d4 T, or AZT. It can present as myopathy (proximal muscle weakness, tenderness, myalgias, and elevated CPK), lipoatrophy, peripheral neuropathy, and hyperlactatemia. A serum lactate should be checked in any HIV patient taking an NRTI and presenting with nausea, vomiting, abdominal pain, weight loss, or anorexia. Patients with symptomatic lactic acidosis need hospital admission and cessation of antiretrovirals, as they have a high risk of death (21).

The NNRTIs are noncompetitive inhibitors of reverse transcriptase and block RNA-dependent and DNA-dependent DNA polymerase activity. Rash is the most frequent side effect associated with the NNRTIs, with a small minority of patients ($<5\%$) developing Stevens–Johnson syndrome. Symptomatic hepatitis, including fatal hepatic necrosis, has been reported with use of nevirapine. In contrast, most NNRTIs may cause asymptomatic hepatic transaminase elevations, which are relatively benign.

PIs prevent viral replication by blocking activation of viral protein precursors. PIs are associated with a high frequency of side effects. Short-term effects are principally GI (including nausea, diarrhea, and bloating). Long-term effects are metabolic, including insulin resistance, hyperlipidemia, and fat redistribution. PI therapy is associated with an increased risk of coronary atherosclerosis. Other significant side effects of PIs include fulminant hepatitis associated with tipranavir, interaction with some statins to increase the risk of rhabdomyolysis, and an increased risk of bleeding in hemophiliacs (7).

Additional newer classes of drugs include entry/fusion inhibitors and integrase inhibitors. Entry/fusion inhibitors prevent HIV entry into cells by targeting specific viral surface proteins or their corresponding receptors. Enfuvirtide and maraviroc are two entry/fusion inhibitors currently approved for use in combination

with other antiviral agents only in treatment-experienced patients. Major side effects include local injection site reactions and increased rate of bacterial pneumonia (enfuvirtide). Raltegravir is the only integrase inhibitor currently approved for use in patients who have limited or no treatment options. Common side effects include diarrhea, nausea, headache, and fever.

The goal of ART is to reduce viremia, boost the CD4 cell count, halt disease progression, prevent development of resistant variants, and improve the quality of life. The current United States consensus recommendations for initiation of ART are detailed in Table 191.5. The current United States Department of Health and Human Services (DHHS)-recommended first-line ART regimens typically combine two NRTIs with either an NNRTI, a ritonavir-boosted PI, or an integrase inhibitor. Treatment strategies are tailored to the individual patient with special consideration to tolerability, comorbidities, adverse effect profile, drug-to-drug interactions, convenience, and likelihood of adherence. Decisions regarding initiation or change in antiretroviral medications should be made in consultation with the patient's primary care provider or an infectious disease consultant.

TABLE 191.5
Currently Accepted Indications for Initiation of ART in HIV Infection (7)

- CD4 <500 cells/mm^3

OR

- History of an AIDS-defining illness (see Table 191.1)

Any of the following independent of CD4 cell count:

- Symptomatic HIV infection
- Pregnancy
- HIV-associated nephropathy
- Hepatitis B (HBV) or C (HCV) coinfection
- CD4 cell count decreasing by >100 cells/mm^3/yr
- Viral load >100,000 cells/ml
- High cardiovascular disease risk
- High risk of transmission to an uninfected person
- >60 yrs old

Immune reconstitution syndrome can develop weeks to months after AIDS patients begin ART. It is associated with an atypical immune response to latent and subclinical infections presenting with a paradoxical worsening of pre-existing infectious processes as immune function improves. It is a diagnosis of exclusion and should be considered in any HIV patient who recently started or restarted ART. After other serious infections are ruled out, consultation with an infectious disease specialist is warranted. In addition to treating any underlying infections, therapy may include nonsteroidal anti-inflammatory drugs and/or steroids.

Chemoprophylaxis

Chemoprophylaxis is directed toward preventing initial and subsequent episodes of certain opportunistic infections and includes antibiotic therapy as well as vaccinations. Knowledge of the HIV-infected patient's prophylactic regimen can aid the emergency physician in diagnostic and treatment decisions as well as follow-up recommendations. CD4 cell count is the best predictor of the risk for opportunistic infections and is consequently used to make decisions about antimicrobial prophylaxis. Bactrim DS 1 tab daily is the preferred prophylactic regimen for PCP and toxoplasmosis, given to individuals with CD4 <200 cells/mm^3 and CD4 <100 cells/mm^3, respectively. Individuals with CD4 <50 cells/mm^3 should receive azithromycin 1,200 mg once weekly as prophylaxis against MAC. Other prophylactic regimens include valacyclovir prophylaxis against HSV recurrence, antifungal agents to prevent histoplasmosis and coccidiomycosis, and vaccinations against pneumococcus, varicella zoster, hepatitis A virus (HAV), HBV, HPV, and influenza.

CRITICAL INTERVENTIONS

- Make the presumptive diagnosis of PCP in patients with cough, dyspnea, fatigue, and hypoxia without any other explanation.
- Isolate HIV-infected patients with pulmonary symptoms until TB is excluded.

- Perform a CT and LP to evaluate patients with CD4 cell counts <200 cell/mm^3 who have an altered mental status or headache in which another cause is not clearly identified.
- Admit patients with disseminated varicella zoster disease or ophthalmic zoster to isolation beds for IV acyclovir therapy.

DISPOSITION

Disposition decisions for HIV-infected patients are based, as for any patient, on clinical condition, the availability of outpatient resources, and the ability to arrange adequate follow-up.

Patients who are known to be seropositive for HIV but who are not admitted to the hospital should be referred for follow-up or for medical consultation if they do not have an established source of care. Patients who have symptoms or signs suggestive of HIV infection (e.g., weight loss, generalized adenopathy, chronic diarrhea, oral thrush), but who do not require admission should be tested for HIV and receive similar referral.

Circumstances in which admission may be appropriate are similar to other chronically ill and immunocompromised patients. In addition, fever without a source, suspected PCP, new CNS symptoms, intractable diarrhea, and potential retinal infections are especially significant in AIDS patients. When there is doubt about diagnostic or management options, consultation with an infectious disease specialist, neurologist, or AIDS specialist is appropriate.

PREVENTION AND PRECAUTIONS

Numerous studies have shown that a substantial proportion of patients in the ED have unsuspected HIV infection and that HIV seroreactivity cannot be accurately predicted. Because there is no cure for HIV, frequent hand washing, gloves, gown, mask, and eye protection are a necessity when exposure to blood or body fluids is possible. It should be noted, however, that the risk of acquiring HIV through occupational exposure appears to be very low. Transmission risk is estimated at 0.3% for percutaneous exposures and 0.09% for mucocutaneous exposures (7).

The US DHHS provides specific guidelines for emergency physicians caring for health care workers after an occupational exposure to HIV. The policies were most recently updated in 2013 (22), and include significant changes to the 2005 recommendations. For complicated cases, the National HIV/AIDS clinicians' consultation center provides a Postexposure Prophylaxis hotline. The hotline is available 24 hours a day at 888–448–4911. See Chapter 194 in this text for specific recommendations.

Common Pitfalls

- Failure to recognize undiagnosed infection. Because patients often may not volunteer information regarding HIV risk factors, this information must be actively sought whenever a patient with possible opportunistic infection or other symptoms suggestive of HIV infection (e.g., weight loss, fever) is being treated.
- Failure to fully evaluate nonspecific respiratory complaints in those with HIV—particularly later stage disease. Shortness of breath may be the only complaint in patients with PCP. CT should be considered in those with a negative chest x-ray and dyspnea on exertion.
- Failure to fully evaluate complaints of fever in HIV-positive patients who appear well. Fever may indicate systemic infection; blood cultures should be obtained, even in patients who appear nontoxic.
- Chronic low-grade headache or headache different from a patient's usual pattern of headache may be suggestive of CNS infection or malignancy; a head CT and LP are indicated in such patients.

CHAPTER 192
Toxic Shock Syndromes

Emily Rose

Staphylococcal Toxic Shock Syndrome

Toxic shock syndrome (TSS) associated with *Staphylococcus aureus* is a toxin-mediated, multisystem illness that occurs in primarily healthy people of any age group. It was originally described in 1978. The peak reported incidence, in 1980, was linked to the use of highly absorbent tampons containing polyacrylate rayon. Owing to federal regulations for tampons and public awareness, the incidence of TSS has declined. The incidence of TSS and probable TSS (including menstrual and nonmenstrual categories) is 1 to 3 per 100,000 with a case : fatality rate of 3% to 10% (1,2). The majority of reported cases of TSS have been due to methicillin- susceptible *S. aureus* (MSSA), but cases due to methicillin-resistant *S. aureus* (MRSA) have emerged in association with increased rates of community-acquired MRSA infections (3). Staphylococcal TSS cases are now occasionally associated with necrotizing fasciitis and myositis (1).

Nonmenstrual staphylococcal TSS currently accounts for approximately half of all cases and may occur with any type of *S. aureus* infection. Clinical scenarios associated with nonmenstural TSS include surgical and postpartum wound infections, mastitis, septorhinoplasty, sinusitis, osteomyelitis, arthritis, burns, skin lesions (including varicella zoster), respiratory infections (e.g., influenza, tracheitis, pharyngitis), HIV infection, and enterocolitis. Occasionally, no source is found (3,4). Influenza associated with TSS has a mortality as high as 90% (5). Patients with AIDS may develop

recalcitrant erythematous desquamating disorder, a prolonged clinical course with severe and persistent desquamation (6).

TSS is a superantigen-mediated disease mediated by *S. aureus exotoxins*. Superantigens may activate up to 20% of T cells at one time, resulting in massive cytokine production (1,3). These cytokines are responsible for capillary leak syndrome and account for many of the clinical signs of TSS. Toxic shock syndrome toxin-1 (TSST-1) was the initial exotoxin isolated from *S. aureus* isolates associated with TSS in 1981 (1,7). It is the cause of nearly all menstrual cases of TSS because of its superior ability over other superantigens to penetrate mucosal surfaces (1). Oxygen is required for TSST-1 production. Tampons introduce oxygen into the typically anaerobic human vagina which allows TSST-1 proliferation and mucosal penetration. TSST-1 also causes approximately 50% of nonmenstrual TSS.

Numerous other superantigens, most commonly staphylococcal enterotoxins B and C, contribute to nonmenstrual TSS. Host antibody responses to the *S. aureus* exotoxins play an important role in the pathogenesis of TSS. Up to 40% of humans may be colonized with *S. aureus* and those with damaged skin such as atopic dermatitis are almost always colonized on skin surfaces (1). Approximately 70% to 80% of those in late teenage years and 90% to 95% of individuals in the fourth decade have developed antibodies to TSST-1. Passive immunity is conferred to babies at birth but wanes with time (3). Patients with clinical TSS lack antibody to TSST-1 and often fail to develop appropriate antibodies in their serum secondary to toxin-mediated excessive inflammatory response, cytokine production, and inhibition of antibody production (1). Only 50% of patients develop antibodies after TSS (4,6). Lack of protective antibodies places patients at risk for recurrent TSS and up to one-third of patients will have recurrence (6).

CLINICAL PRESENTATION AND ED EVALUATION

The most common features of TSS include fever, hypotension, and rash. Patients often present with an abrupt onset of flu-like symptoms including fever, malaise, myalgias, chills, headache, sore throat, vomiting, diarrhea, abdominal pain, or dizziness. Severe hypotension can be relatively unresponsive to fluids, last for days, and lead to tissue ischemia, encephalopathy, and organ failure.

A major feature of TSS is the erythematous rash, resembling sunburn, which may be diffuse or patchy in distribution and involves the palms and soles. The rash may be subtle and fleeting, complicating diagnosis. There may also be hyperemia of the conjunctiva, pharynx, tongue, and vaginal mucosa. Desquamation of the skin occurs in 7 to 14 days at the sites of the previous rash. A delayed pruritic maculopapular rash may also occur with desquamation weeks after the disease (3).

Criteria for the diagnosis of staphylococcal TSS defined by the Center for Disease Control (CDC) are provided in Table 192.1. However, TSS can involve every organ system and can produce a wide constellation of symptoms. The diagnosis should be considered if even all criteria are not met.

TABLE 192.1
Criteria for Staphylococcal Toxic Shock Syndrome

1. Fever ≥102°F (38.9°C)
2. Presence of diffuse macular erythroderma ("sunburn" appearance)
3. Desquamation 1 to 2 wks after onset of illness, particularly of the palms and soles
4. Hypotension, defined as a systolic blood pressure of 90 mm Hg for adults and less than the fifth percentile for children younger than 16 years; an orthostatic decrease in diastolic blood pressure of 15 mm Hg with a position change from lying to sitting; orthostatic syncope; or orthostatic dizziness
5. Involvement of three or more of the following organ systems:

   Gastrointestinal: history of vomiting or diarrhea at the onset of illness

   Muscular: elevated creatine phosphokinase level greater than two times the upper limit; or severe myalgia

   Mucous membrane: nonpurulent conjunctivitis, oropharyngeal hyperemia, or vaginal hyperemia or discharge

   Renal: BUN or creatinine greater than two times the upper limit or pyuria (>5 WBC/hpf)

   Hepatic: elevated serum transaminase and bilirubin levels

   Hematologic: thrombocytopenia (<100,000/μL)

   Central nervous system: disorientation or alteration in consciousness without focal neurologic signs and in the absence of hypotension or fever

   In addition, normal results of the following tests, if performed:

   Blood, throat, cerebrospinal fluid cultures (blood culture may be positive for *Staphylcoccus aureus*); antibody tests for Rocky Mountain spotted fever, ehrlichiosis, leptospirosis, and rubella

Toxic shock syndrome is "probable" when at least four of the five criteria are fulfilled.

Modified from American Academy of Pediatrics. Staphylococcal infections. In: Pickering LK, ed. *Red Book: 2012 Report of the Committee on Infectious Diseases.* 29th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2012:653–668.

The clinical presentations of menstrual and nonmenstrual TSS are similar. Super antigen toxins (such as TSST-1) have the ability to inhibit the migration of polymorphic neutrophils (PMNs) to infection and often there is a lack of inflammation around the site of infection. Surgical wound sites and cutaneous infections that harbor toxin-producing *S. aureus* are frequently benign appearing and without with obvious purulence (5).

The diagnosis of TSS is often made on clinical grounds and must be considered in a hypotensive febrile patient with a rash (on examination or by history). The disorder is toxin mediated; therefore, blood cultures are rarely positive (5%) (3). Isolation of *S.*

aureus is not required for the diagnosis of staphylococcal TSS, though 80% to 90% of patients with TSS have *S. aureus* isolated from the mucosa or wound sites. Laboratory examination may demonstrate signs of multiorgan involvement including thrombocytopenia (platelets $<100{,}000$), elevated blood urea nitrogen (BUN) and creatinine, and elevated liver function tests.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of TSS includes *streptococcal* TSS (discussion to follow), Kawasaki disease, staphylococcal scalded-skin syndrome, scarlet fever, Stevens–Johnson syndrome, Rocky Mountain spotted fever, ehrlichiosis, leptospirosis, meningococcemia, typhoid fever, dengue hemorrhagic fever, atypical measles, viral illness, anaphylaxis, heat stroke, gram-negative sepsis, and drug reactions.

ED MANAGEMENT AND DISPOSITION

Initial treatment consists of intravenous fluid replacement. Large volumes (10 to 20 L) of crystalloid are often required to maintain normal perfusion. Hemodynamic monitoring and vasopressors are sometimes necessary. Tampons, nasal packs, or other foreign bodies must be removed. Surgical wounds or areas of infection need to be irrigated; abscesses must be incised and drained. Cultures of the vaginal canal or of the infectious focus or surgical wound should be submitted for culture and susceptibility testing, as TSS is caused by both MSSA and MRSA.

Antibiotics may not affect the clinical course but may be beneficial if the patient is bacteremic or if there is a site of ongoing infection. Antibiotic therapy reduces the likelihood of recurrent TSS in those that previously failed to develop an appropriate antibody response to staphylococcal toxins (1,3,8). Clindamycin (600 to 900 mg IV every 8 hours) suppresses protein synthesis and toxin production. Vancomycin (10 to 20 mg/kg/dose) is added to cover MRSA. If culture and susceptibility results are available and indicate MSSA, clindamycin plus oxacillin or nafcillin are recommended.

Commercially available intravenous immune globulin (IVIG) has anti–TSST-1 antibodies present in varying amounts which may neutralize the toxin in TSS. Many experts recommend its use in severe cases. However, there are no data from controlled clinical trials demonstrating a reduction in morbidity or mortality with the use of IVIG. Risk versus benefit should be considered prior to its use. The role of steroids is unclear and not currently recommended.

Patients with suspected TSS should be admitted to the hospital. Unstable patients should be admitted to the intensive care unit.

Common Pitfalls

- Failure to recognize TSS in young healthy patients with fever and an erythematous rash
- Failure to administer adequate fluid volumes to maintain tissue perfusion
- Failure to seek an occult source of staphylococcal colonization or infection
- Failure to debride or irrigate benign-appearing wounds
- Failure to remove foreign bodies

Streptococcal Toxic Shock Syndrome

In the late 1980 s, a disease similar to staphylococcal TSS, but caused by a strain of group A streptococci (GAS), was recognized (9). This illness, characterized by hypotension and multiorgan failure, was termed *streptococcal toxic shock syndrome* (STSS). The Centers for Disease Control and Prevention case definition of this syndrome is shown in Table 192.2.

TABLE 192.2
Case Definition for the Streptococcal Toxic Shock Syndrome

1. Isolation of group A streptococci
   A. From a normally sterile site (e.g., blood, cerebrospinal fluid, peritoneal fluid, tissue biopsy, surgical wound)
   B. From a nonsterile site (e.g., throat, superficial skin lesion)
2. Clinical signs of severity
   A. Hypotension: systolic blood pressure 90 mm Hg in adults or less than fifth percentile for age in children, and
   B. Two or more of the following signs:
      Renal impairment: creatinine 2 mg/dL for adults or at least twice the upper limit of normal for age
      Coagulopathy: platelets <100,000/μL or disseminated intravascular coagulopathy
      Liver involvement: serum alanine aminotransferase, aspartate aminotransferase, or total bilirubin concentrations at least twice the upper limit or normal for age
      Adult respiratory distress syndrome
      A generalized erythematous macular rash that may desquamate
      Soft tissue necrosis, including necrotizing fasciitis or myositis, or gangrene

An illness fulfilling criteria 1 A and 2 (A and B) can be defined as a definite case.

An illness fulfilling criteria 1B and 2 (A and B) can be defined as a probable case if no other etiology for the illness is identified.

Modified from American Academy of Pediatrics. Group a streptococcal infections. In: Pickering LK, ed. *Red Book: 2012 Report of the Committee on Infectious Diseases.* 29th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2012:668–680.

Group A streptococcal TSS, like staphylococcal TSS, is mediated by toxins that act as superantigens and cause significant release of inflammatory cytokines. Initial infection most commonly occurs through the skin, vagina, or pharynx. Cases of STSS are often associated with minor nonpenetrating trauma or soft tissue infection (10–12). Viral infections, such as varicella and influenza, are thought to provide a portal of entry in other cases, but in many patients, no source of the organism can be identified. Bacterial toxins produced by GAS, particularly streptococcal pyrogenic exotoxins (SPEs), as well as host factors, are thought to play an important role in determining disease severity (13). In contrast to staphylococcal TSS, blood cultures are generally positive (60%). Streptococcal TSS often occurs in the presence of necrotizing fasciitis and myositis. Young children, the elderly, and the

immunosuppressed are at greatest risk, but a large proportion of patients with STSS are young, healthy adults. Risk factors for GAS infection include minor trauma, soft tissue injuries (hematoma, bruising or muscle strain), surgical procedures, viral infections (especially influenza and varicella), and use of nonsteroidal anti-inflammatory drugs (NSAIDs) (13). It is unclear if the association of STSS with NSAIDs is causal, but NSAID use may mask presenting symptoms and contribute to a delay in diagnosis. Invasive GAS infections are increasing in frequency with an estimated 3.5 cases per 100,000 and a case : fatality rate of 36% to 43% for STSS (13).

CLINICAL PRESENTATION AND ED EVALUATION

Streptococcal TSS is typically an acute illness with fever, rapid-onset hypotension, and signs of multiorgan involvement including rapidly progressive renal failure. Flu-like symptoms such as malaise, myalgias, nausea, vomiting, and diarrhea often occur. In distinction to staphylococcal TSS, the diffuse scarlatina-like rash is uncommon in STSS (<10%). Patients often have signs of soft tissue infection such as localized swelling and erythema. The extremities are most commonly affected, but the chest, abdomen, or pelvis may be involved. Pain out of proportion to physical findings, rapid escalation of pain and the presence of vesicles or bullae on the skin are concerning signs of progression to necrotizing fasciitis. About 20% of STSS occur without soft tissue findings. Invasive infections such as pneumonia, pleural empyema, osteomyelitis, pyarthrosis, endophthalmitis, peritonitis, myocarditis, endocarditis, postpartum infections, or overwhelming sepsis may occur in association with STSS (13). Streptococcal TSS nearly always occurs in association with bacteremia (1). Complications include acute respiratory distress syndrome (ARDS), disseminated intravascular coagulation (DIC), and renal failure (often requiring dialysis).

ED MANAGEMENT AND DISPOSITION

Essential management of STSS includes hemodynamic support, early antibiotic therapy, and, when indicated, surgical therapy.

Massive quantities of intravenous fluids (up to 20 L/d) may be necessary to maintain perfusion secondary to intractable hypotension and diffuse capillary leak. Vasopressors may also be required.

Early treatment with antibiotics is critical. Broad-spectrum coverage should be used. Clindamycin is first-line therapy as it suppresses the synthesis of bacterial toxins and has been associated with better outcomes than β-lactam antibiotics alone in patients with STSS (14). In addition to clindamycin (900-mg IV every 8 hours), a carbapenem (imipenem 500 mg every 6 hours or meropenem 1 g every 8 hours) or a combination of drug containing penicillin plus a β-lactamase inhibitor (ticarcillin–clavulanate 3.1 g every 4 hours or piperacillin–tazobactam 4.5 g every 6 hours) should be used (14).

Significant pain to the soft tissue must trigger suspicion for serious infection such as myositis or necrotizing fasciitis regardless of lack of erythema or history of seemingly insignificant trauma. These serious infections require prompt and aggressive surgical debridement. Early surgical consultant is of paramount importance to reduce morbidity and mortality.

IVIG is also recommended by several experts in STSS but the supporting data are limited (14). Anecdotal reports of hyperbaric oxygen have been used in a handful of patients (14).

Patients with suspected TSS should be admitted to the hospital. Unstable patients should be admitted to the intensive care unit.

KEY TESTING

Toxic Shock Syndromes

- CBC
- Electrolytes, BUN, creatinine, glucose
- Liver function tests/liver enzymes
- PT/PTT/INR
- Lactate
- Urinalysis
- Blood cultures

- Wound culture if wound present
- Throat culture if pharyngitis
- CSF if suspected meningitis
- CXR

CRITICAL INTERVENTIONS

- Toxic Shock Syndromes
- Administer aggressive intravenous fluid replacement to maintain perfusion.
- Remove tampons, nasal packs, surgical dressings, or other foreign bodies.
- Incise and drain abscesses, irrigate surgical wounds, and debride areas of infection.

Common Pitfalls

- Failure to consider the diagnosis of STSS early and to institute antibiotics promptly
- Failure to debride soft tissue infections aggressively
- Failure to recognize pain out of proportion to examination even without physical findings could be a sign of STSS

CHAPTER 193

Parasitic Disease

Meghan A. Cummins and Keith T. Borg

Parasitic infestations are much more widespread than many people realize. Parasites affect not only impoverished people in remote countries but can also cause important health problems for the rich and poor throughout the world, including the United States. Parasites are considered by many physicians to be the most undiagnosed infectious disease challenge in the United States today. Diagnosing parasitic infections in the emergency department (ED) can be challenging because there is a large and varied group of organisms that cause parasitic infections with a wide range of clinical symptoms. Parasitic disease, however, can usually be diagnosed through methods available to most emergency physicians, and effective treatments are available that are generally minimally toxic to the human host (1,2). A history of foreign travel or habitation in an endemic area, including certain regions of the United States, should alert the clinician to the possibility of parasitic infection. As with many disease processes, the key is considering parasitic infestation in the differential diagnosis.

Symptoms may not manifest themselves until well after the traveler has returned home. In addition, over the past two decades, the proportion of the US population born abroad has increased steadily, with newer immigrants typically coming from Latin America and Asia (3). The proper treatment of immigrants in the United States requires a familiarity with diseases common in the developing world, such as malaria, amebiasis, and neurocysticercosis. Given the constant change in the globalization of infectious disease, the clinician should always consult current

references, including the Centers for Disease Control (CDC) website (http://www.cdc.gov/travel). Parasitic infestation is a global problem. Here in the United States, the CDC cites food as the catalyst behind 80% of the pathogenic outbreaks.

Four major groups of organisms infest humans. *Protozoans* cause malaria, amebiasis, giardiasis, and many other diseases. Helminths, or worms, including *nematodes* (roundworms), *cestodes* (tapeworms), and *trematodes* (flukes), are also responsible for a wide variety of human illnesses. A comprehensive review of parasitic diseases would encompass infections due to literally scores of organisms, so this chapter is limited to the parasitic diseases most common in EDs in the United States (trichomoniasis is excluded). This chapter is divided into three discussions: systemic illnesses (malaria), predominantly gastrointestinal (GI) disease, and predominantly central nervous system (CNS) disease (cysticercosis).

Malaria

CLINICAL PRESENTATION

Awareness about malaria and measures that travelers can take to avoid infective mosquito bites are more important than ever. Cases of malaria continue to rise in the United States. Thus, fever in a patient with a history of recent travel or habitation in the tropics should suggest the diagnosis of malaria. Caused by four species of the protozoan *Plasmodium* (*P. vivax, P. ovale, P. falciparum,* and *P. malariae*), malaria is the most common parasitic disease in the world. According to the CDC (www.cdc.gov/malaria), malaria currently infects an estimated 350 to 500 million people worldwide and on average, 1,500 cases are reported in the United States annually. Malaria causes <1 million deaths annually (most commonly children in sub-Saharan Africa). Although malaria is no longer considered endemic in the United States, increased immigration from and travel to countries where the disease is common has made malaria more frequent as a presenting complaint in ED in this country (4). The number of cases of malaria acquired by international travel is growing as a result of the increased risk of malaria transmission

where malaria control has faded and also because of the spread of drug-resistant strains of malaria (5). Patients with malaria are frequently misdiagnosed on their initial presentation to the ED, thus increasing their risk for serious morbidity and mortality.

Classic symptoms of malaria:

- Fever, chills, and rigors lasting 4 to 10 hours, culminating in an episode of profuse diaphoresis followed by defervescence.
- This pattern may recur at 2- or 3-day intervals, depending on the species of *Plasmodium* involved.
- General malaise, headache, and, occasionally, hypotension.
- Splenomegaly and jaundice may be seen in established infections. (Physical examination is generally not helpful.)
- Laboratory abnormalities include a mild anemia, neutropenia, thrombocytopenia, and increased prothrombin time. Clinical evidence of impaired hemostasis is rare.

The periodicity of the disease can be explained by examining the life cycle of the infecting organism. In the human, the life cycle of the parasite consists of two stages. The initial stage is known as the liver or exoerythrocytic stage. This is where the parasites multiply in hepatocytes and cause them to rupture. The second stage is known as the blood or erythrocytic stage and occurs when parasites are released into the bloodstream and invade the erythrocytes. This is the cause of clinical illness. *Plasmodium* species may be injected into the human circulation following the bite of the *Anopheles* mosquito, after sharing needles or receiving a blood transfusion, and by congenital transmission. Immature sporozoites migrate to the liver, beginning the exoerythrocytic phase, the duration of which is species-dependent. Ultimately, mature parasites (merozoites) are released into the circulation and invade red blood cells, beginning the erythrocytic phase. Replication within red cells is followed 48 to 72 hours later by red cell lysis and release of further merozoites into the circulation, which again invade erythrocytes and repeat the cycle. The fever corresponds to episodes of red cell lysis.

The classic pattern of periodic fever is not always seen, however, particularly early in the course of the illness. The variability of the clinical course also depends on the infecting species and the host's

immune status. People living in endemic areas often have partial "immunity" that results in much less severe manifestations and symptoms. It is presumed to be an acquired immunity caused by frequent exposure to the infecting organism. Months after leaving an endemic area, these persons may experience relapses that resemble the acute form of the disease, probably caused by a loss of immunity and the release of exoerythrocytic parasites from the liver. *P. vivax* and *P. ovale* can persist for long periods in the exoerythrocytic state. Even patients who have received adequate antimalarial therapy may experience relapses associated with the release of exoerythrocytic organisms. Cases have been reported 2 months to 4.5 years after a traveler's return (5).

P. falciparum causes the most severe type of malaria and is responsible for most complications and deaths related to malaria (4). Falciparum malaria has two important features that account for differences in its presentation and in the severity of the disease it produces. First, this species causes widespread capillary obstruction, resulting in end-organ hypoxia and dysfunction, with severe complications that can include CNS dysfunction, hemolytic anemia, hypoglycemia, pulmonary edema, septicemia, renal failure, or splenic rupture. A second distinguishing feature of *P. falciparum* is that, unlike other malarial species that infect only the most mature red cells, it infects red cells of all ages, resulting in a greater degree of hemolysis and anemia and the potential for acute tubular necrosis. Finally, unlike *P. ovale* and *P. vivax,* cases of *P. falciparum* malaria in patients with late presentations are caused by blood-stage parasites that were drug resistant or had survived incomplete prophylaxis.

ED EVALUATION

The diagnosis of malaria is a difficult one to make because of the disease's nonspecific clinical features—fever, chills, headache, and malaise. Because approximately 90% of travelers who contract malaria do not become ill until returning home, the diagnosis should be entertained for anyone presenting to the ED with a febrile illness and a history of travel or habitation in an endemic area. Kain et al. (6) estimated that approximately 30,000 travelers from

industrialized countries contract malaria each year. A high degree of suspicion is necessary for diagnosis by physicians who rarely encounter this disease. The most common incorrect diagnosis is a viral syndrome, but a history of recurrent fever generally distinguishes malaria from these disorders. Other disorders that cause fever and are endemic in foreign countries, such as viral hepatitis, dengue fever, typhoid fever, and amebiasis, should also be considered. Recent data suggest that a significant number of those presenting with malaria do so later than previously thought. More than 35% of malaria-infested travelers in one study developed malaria more than 2 months after their return. This suggests that we may need to modify treatment to more aggressively treat the liver phase of the disease for effective prevention (5).

The standard way to make the diagnosis of malaria is through demonstration of intracellular forms of the parasite on a thin Giemsa-stained peripheral blood smear. If malaria is strongly suspected, negative blood films should be repeated every 12 to 24 hours for total of three sets. Three negative sets make the diagnosis very unlikely. Sometimes, it is necessary to use the thick-smear technique, which usually requires the expertise of a trained technician. New rapid testing by PCR, and even real-time PCR assays for chloroquine-resistant strains of *P. falciparum* malaria, as well as other methods, are being developed and should aid in the rapid diagnosis of malarial infections (7).

Although admittedly rare in the United States, congenital malaria should be considered when the emergency physician is presented with the febrile infant of an immigrant mother. It has been estimated that about 15% to 20% of all cases of malaria brought back to Western countries from recent travelers are in children (8).

ED MANAGEMENT

Management of malaria in the ED is guided by the severity of the infection. Assessment of airway patency and respiratory, circulatory, and neurologic status should be performed in a timely fashion. The emergency physician should be prepared to treat potential complications such as anemia, coagulopathies, pulmonary edema,

azotemia, hypoglycemia, metabolic acidosis, and hypotensive shock (9).

Volume should be restored and fever controlled. Hypotension usually responds well to crystalloid infusion. Fever usually responds to standard cooling measures; for temperatures <104°F, oral antipyretics are likely to be effective. Acetaminophen is recommended rather than aspirin because of the common occurrence of thrombocytopenia. For patients with high-density parasitemia (>10% parasitemia), altered mental status, nonvolume overload pulmonary edema, or renal failure, exchange transfusion may be helpful (10).

Pharmacologic therapy of malaria is outlined in Table 193.1. Antimalaria pharmacotherapy and prophylaxis continue to pose difficult problems. Most antimalarial agents act on the parasites at blood stage and therefore do not prevent late onset illness (5). Chloroquine remains the oral drug of choice (with hydroxychloroquine being second-line treatment) for acute treatment of all infections except those due to chloroquine-resistant *P. falciparum* or *P. vivax* acquired in Papua New Guinea or Indonesia. For chloroquine-resistant *P. falciparum* infection or for severely ill patients with an unidentified malarial infection, the recommended agents include either oral quinine plus doxycycline (tetracycline or clindamycin may be substituted for doxycycline), atovaquone–proguanil, or artemether–lumefantrine. Mefloquine may be used if the other drugs are not available. Patients with *P. vivax* acquired within Papua New Guinea or Indonesia should use atovaquone–proguanil plus mefloquine as first-line therapy and consider quinine plus doxycycline or tetracycline as alternative treatments. Patients with severe malaria (regardless of species or geographic location where contracted) or those who are unable to tolerate oral medications, should be treated with intravenous (IV) quinidine plus tetracycline, doxycycline, or clindamycin.

TABLE 193.1
Treatment of Malaria

Drug	Adult Dosage	Pediatric Dosage
	Nonresistant Malaria	
Oral Drug of Choice:		
Chloroquine phosphate	600 mg base (1 g), then 300 mg base (500 mg) 6 hrs later, then 300 mg base (500 mg)/d × at 24 and 48 hrs	10 mg base/kg (max 600 mg base), then 5 mg base/kg 6 hrs later, then 5 mg base/kg/d × 2 d
Alternative:		
Hydroxychloroquine	800 mg PO followed by 400 mg PO at 6 hrs, 24 hrs, and 48 hrs	10 mg/kg PO then 5 mg/kg PO at 6 hrs, 24 hrs, and 48 hrs
	Chloroquine-Resistant P. Falciparum Malaria	
Oral Drugs of Choice:		
1. Atovaquone–proguanil	4 adult tablets per day for 3 d 1 adult tablet = 250 mg atovaquone/100 mg proguanil	5–8 kg: 2 peds tabs/d × 3 d 9–10 kg: 3 peds tabs/d × 3 d 11–20 kg: 1 adult tab/d × 3 d 21–30 kg: 2 adult tabs/d × 3 d 31–40 kg: 3 adult tabs/d × 3 d >40 kg: 4 adult tabs/d × 3 d Peds tablet = 62.5 mg atovaquone/25 mg proguanil
2. Aretemether–lumefantrine	4 tablets per dose (3-d treatment schedule: initial dose, followed by second dose 8 hrs later, then 1 dose bid for following 2 d)	5–14 kg: 1 tablet per dose 15–25 kg: 2 tablets per dose 25–34 kg: 3 tablets per dose >35 kg: same as adult dose
3. Quinine sulfate plus either:	650 mg q8h × 3 d–7 d (3-d infections acquired outside SE Asia, 7-d infections acquired in SE Asia)	10 mg/kg PO q8h × 3 d–7 d (3-d infections acquired outside SE Asia, 7-d infections acquired in SE Asia)
a. Clindamycin (PO or IV)	PO: 20 mg/kg/d PO divided 3 times daily × 7 d IV: 10 mg/kg loading dose then 5 mg/kg every 8 hrs; switch to oral meds ASAP; total treatment course of 7 d	Same as adult
b. Doxycycline (PO or IV)	PO: 100 mg PO bid × 7 d IV: 100 mg IV bid; switch to oral meds ASAP; treatment course 7 d	PO: 2.2 mg/kg PO bid × 7 d IV: Children <45 kg receive 2.2 mg/kg IV bid then switch to PO ASAP Children >45 kg is same as adults Treatment course is 7 d
c. Tetracycline	PO: 250 mg PO qid × 7 d IV: Dosage is the same as for PO	PO: 25 mg/kg/d PO divided qid × 7 d IV: Same as for PO
Alternative:		
3. Mefloquine	750 mg PO followed in 6–12 hrs by 500 mg	15 mg/kg PO followed in 6–12 hrs by 10 mg/kg
	Chloroquine-Resistant P. Vivax Malaria	
Drug of Choice:		
Atovaquone–proguanil plus mefloquine	As above	As above
Alternative:		
1. Quinine sulfate plus		
a. doxycycline	As above	As above
b. Clindamycin	As above	As above
c. Tetracycline	As above	As above
	Prevention of Relapses (P. Vivax and P. Ovale only)	
Primaquine phosphate	30 mg PO daily × 14 d	0.5 mg base/kg/d × 14 d
	Severe Malaria or Patient Unable to Take PO MEDS	
Parenteral Drug of Choice:		
Quinidine gluconate	10 mg/kg loading dose (max 600 mg) in normal saline slowly over 1–2 hrs, followed by continuous infusion of 0.02 mg/kg/min until oral therapy can be started	Same as adult dose
Alternative:		
1. Quinidine gluconate plus	24 mg/kg loading dose infused over 4 hrs followed by 12 mg/kg infused over 4 hrs every 8 hrs after the loading dose	Same as adult dose
a. Doxycycline	As above	As above
b. Clindamycin	As above	As above
c. Tetracycline	As above	As above

Adapted from Griffith KS, Lewis LS, Mali S, et al. Treatment of malaria in the United States: A systematic review. *JAMA*. 2007;297(20):2264–2277.

Critically ill patients should have access to continuous cardiac and blood pressure monitoring, while having frequent blood glucose, hemoglobin, parasitemia levels, and electrolyte levels checked. As

stated previously, exchange transfusion may be indicated in patients who meet clinical criteria (10). Finally, newer artemisinin-derived drugs similar to artemether–lumefantrine, such as dihydroartemisinin–piperaquine and artesunate–mefloquine are being tested against multidrug-resistant strains of *P. falciparum* (11–13).

In addition to acute therapy, patients infected with *P. vivax* or *P. ovale* require more prolonged treatment to prevent reactivation of exoerythrocyte forms. These patients should be treated with primaquine phosphate, 30 mg base/d for 14 days for adults and 0.5 mg base/kg/d for 14 days for children. Patients should be screened for G-6-PD deficiency before beginning primaquine therapy, and the drug is contraindicated during pregnancy. Patients who are G-6-PD deficient and for whom primaquine is thus contraindicated should be counseled about the possibility of recurrence (10).

To prevent fatal outcomes in cases of falciparum malaria, the following are required: improved health information and preventive measures for the 30 million travelers who visit regions where malaria is endemic, improved recognition of infection by physicians, and prompt initiation of effective therapy (6).

DISPOSITION

Hospital admission is indicated for patients with severe dehydration, significant underlying medical illness, inability to tolerate oral medications, or evidence of end-organ involvement such as stroke, renal failure, or pulmonary edema. Those whose ability to comply with an outpatient regimen is questionable should also be admitted. Suspected *P. falciparum* infection is commonly considered to require hospitalization because of the increasing prevalence of drug resistance and the potential for life-threatening complications. Severely ill patients or those with significant parasitemia ($>3\%$ of red cells containing parasites) should be treated in an intensive care unit with IV medications.

Prophylaxis is the most important aspect of malaria control in the United States, given the frequency of foreign travel. Before going to an endemic area, travelers should consult an expert to determine

whether chemical prophylaxis is indicated and whether chloroquine resistance has been reported in the area. Decisions about prophylaxis are increasingly complicated as a result of malaria drug resistance. Chloroquine is usually recommended for persons traveling to endemic areas but may not be necessary in all cases, particularly for a short trip to an urban area. When traveling to a chloroquine-resistant area, another drug should be chosen. The particular medication chosen must depend on the pattern of resistance in the area. Malarone (atovaquone/proguanil) is the prophylactic drug of choice for adults traveling to most chloroquine-resistant areas. Other options include mefloquine (Lariam), doxycycline, and hydroxychloroquine sulfate (Plaquenil). Primaquine is also an option for prophylaxis specifically against *P. vivax* for trips of short duration only. See Table 193.2 for prophylactic drug dosages.

TABLE 193.2
Malaria Prophylaxis Drug Regimes

Medication	Adult Dose	Pediatric Dose	Initiation/Termination
Chloroquine	500 mg (300 mg base) per week	5 mg/kg base (8.3 mg/kg) per week	Begin 1–2 wks before and continue 4 wks after travel completed
Malarone • Adult tablet = atovaquone 250 mg/ proguanil 100 mg • Pediatric tablet = atovaquone 62.5 mg/proguanil 25 mg	One adult tablet per day	5–8 kg = ½ peds tab/d 9–10 kg = ¾ peds tab/d 11–20 kg = 1 peds tab/d 21–30 kg = 2 peds tab/d 31–40 kg = 3 peds tab/d >40 kg = 1 adult tab/d	Begin 1–2 d before and continue 1 wk after travel completed
Mefloquine (Lariam)	250 mg (228 mg base) tablet per week	5–10 kg = ⅛ tab/wk 11–20 kg = ¼ tab/wk 21–30 kg = ½ tab/wk 31–45 kg = ¾ tab/wk >45 kg = 1 tab/wk	Begin 1–2 wks before and continue 4 wks after travel completed
Doxycycline	100 mg/d	2 mg/kg/d in children older than 8 yrs up to adult dose	Begin 1–2 d before and continue 4 wks after travel completed
Hydroxychloroquine sulfate (plaquenil)	400 mg (310 mg base) per week	5 mg of base/kg up to adult dose	Begin 2 wks before and continue 4 wks after travel completed
Primaquine	52.6 mg (30 mg base) daily	0.8 mg/kg (0.5 mg/kg base) up to adult dose daily	Begin 1–2 d before and continue 1 wk after travel completed. Only use for prophylaxis for short duration travel in areas with *P. vivax*.

Contraindications to the use of mefloquine include serious psychiatric illness, seizures, or serious cardiac arrhythmias (14). Because no drug regimen guarantees protection against malaria, if fever develops within the first year after travel to a malarious area, travelers should be encouraged to seek medical attention (10).

Consultation of current guidelines for areas of travel can be obtained from the CDC or WHO websites.

Gastrointestinal Disease

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The GI tract is commonly affected by parasites. This is because exposure occurs readily through fecal contamination of food and water. Protozoans and helminths are common causes of GI symptoms such as abdominal pain, malabsorption, obstruction, diarrhea, rectal prolapse, and pruritus ani. The protozoans that cause GI diseases include *Giardia lamblia, Entamoeba histolytica,* and *Cryptosporidium.*

G. lamblia, a flagellated protozoan, affects the small intestine. It is the most commonly identified intestinal parasite in the United States. This infection may be transmitted through the ingestion of contaminated food or water, by person-to-person contact, or through fecal–oral transmission (15). Patients may experience explosive, watery, foul-smelling diarrhea or may express a more insidious onset of symptoms. Cramping epigastric pain is common; bloody diarrhea is unusual. Physical examination of the abdomen often reveals diffuse upper quadrant tenderness without evidence of peritoneal irritation. Malabsorption may be responsible for the substantial weight loss that is associated with *Giardia* infestations in more than 50% of patients (15). Microscopic stool examination may demonstrate active trophozoites, but cysts are more commonly found. At least three stools taken at 2-day intervals should be examined for ova and parasites. Commercially available tests to detect *Giardia* antigen in the stool exist. The “string test” may be used in an outpatient setting to help diagnose *Giardia* infestation. This test involves the patient swallowing a gelatin capsule attached to a string. The string slowly works its way into the duodenum over 4 to 6 hours, at which time it is pulled up and any blood or other material from the digestive tract still attached to the string is looked at under a microscope. Parts of the parasites or eggs may be observed in a positive test. Because *Giardia* is most often transmitted

by contaminated water or by the fecal–oral route, efforts at prevention should focus on these routes of transmission.

E. histolytica, upon invasion of the colonic mucosa, can cause amebic dysentery with abdominal pain, tenesmus, and bloody stools (16). It may result in severe dehydration. The large bowel is typically most affected. Transmission of amebiasis is linked directly to hygiene and sanitation; risk factors for amebiasis include recent travel and institutionalization. The spectrum of clinical disease ranges from mild diarrhea to fulminant rectocolitis. Massive GI bleeding may occur when amebic trophozoites invade large areas of colonic mucosa and cause ulceration; toxic megacolon, perforation, and peritonitis are other severe complications of amebic dysentery. Extraintestinal infection, most commonly amebic liver abscess (3), may occur with invasion of the trophozoites through the colonic mucosa. The diagnosis of amebic dysentery is made by stool examination for cysts and trophozoites or in biopsy specimens obtained by sigmoidoscopy or colonoscopy (16). More recently, PCR assay techniques have shown greater sensitivities and specificities for both *E. histolytica* and *Entamoeba dispar* species than stool microscopy or culture (17).

Cryptosporidium may affect any part of the GI tract. Immunocompetent patients frequently experience a clinical syndrome similar to that of giardiasis, whereas immunodeficient patients typically develop more serious disease and may die of dehydration and electrolyte abnormalities. In addition to water sources, such as drinking water, pools, lakes, and water parks, there have been several food-borne outbreaks of cryptosporidiosis in North America, including the severe outbreak in Milwaukee (18). Diagnosis is based on the microscopic identification of fecal oocysts, although newer more sensitive techniques, including molecular methods such as PCR, are being used in reference laboratories to identify *Cryptosporidium* at the species level. The disease is typically self-limited. Paromomycin has been used to treat cryptosporidiosis in several cases. Treatment with nitazoxanide, 500 mg twice daily (either in tablet or suspension form) for 3 days, has shown some

promise in treating enteritis and diarrhea caused by *Cryptosporidium* (19).

Infection with the helminths *Ascaris lumbricoides* and *Strongyloides stercoralis* and the hookworms *Necator americanus* and *Ancylostoma duodenale* causes cramping upper abdominal pain when associated with large worm burdens. Patients presenting from tropical climates, particularly Central America, South America, and Southeast Asia, may be infested with more than one of these GI parasites. Hookworms are also endemic in the southeastern United States.

Infection with *A. lumbricoides* and *S. stercoralis* may present with nonspecific abdominal pain and diarrhea. *Ascaris,* a roundworm, can migrate into the biliary system through the ampulla of Vater and induce inflammation and fibrosis of the biliary ducts through chemical irritation. They may also cause partial or intermittent obstruction of the bile ducts (20). Midepigastric and right upper quadrant pain may also mimic peptic ulcer disease. *Ascaris* has also been reported to cause bowel obstruction, especially in children (21). Upper respiratory symptoms can develop due to pulmonary migration of larvae (Loeffler syndrome). *S. stercoralis* larvae may mature within the GI tract, as the gravid adult female releases rhabditiform larvae that rapidly evolve into the invasive filariform larval form. The filariform larvae can penetrate the GI tract or perianal skin, causing the hyperinfection syndrome characteristic of strongyloidiasis (2); this is particularly likely to appear in the immunocompromised patient. Both *Necator* and *Ancylostoma* penetrate the mucosa of the small bowel in heavy acute infestations and cause cramping epigastric pain. In addition, GI blood loss at worm attachment sites may result in a profound hypochromic microcytic anemia.

The physical examination of patients with worm infestation is often unremarkable. Minimal diffuse upper abdominal tenderness may be present, but peritoneal signs are unusual when the worms are intraluminal. Presentation as an acute abdomen does occur, however, when there is complete biliary obstruction or small bowel obstruction secondary to a massive worm burden, as may be the case with acute *Ascaris* infestation. A “whirlpool” pattern of intraluminal

worms may be seen with plain abdominal x-rays (21). In ascariasis and hookworm disease, microscopic examination of the stool often reveals typical ova. Rhabditiform and filariform larvae of strongyloidiasis may be seen in stool samples and Papanicolaou-stained gastric aspirate or sputum smears. The larval forms of *S. stercoralis* are more likely than ova to be visible in the stool samples from these patients. Eosinophilia is common with all helminthic infections and should alert the clinician to this possibility.

Trichuris trichiura and *Enterobius vermicularis* often present as an annoyance rather than the cause of serious illness. Rectal prolapse may occur with massive infestation by *T. trichiura,* the whipworm, particularly in children (1). Large worm burdens with *T. trichiura* may cause a clinical pancolitis and a mild chronic illness (22), which is referred to as "trichuris dysentery syndrome": chronic diarrhea, anemia, and growth retardation (22). In patients with rectal prolapse from trichuriasis, the adult worms are normally visible on the exposed rectal mucosa. Microscopic examination of stool samples demonstrates the typical barrel-shaped ova of *T. trichiura.*

Infestation with the pinworm *E. vermicularis* is the most common helminthic infection of humans, with the prevalence highest among children ages 5 to 10 (9). Pinworm infection causes severe perianal pruritus, especially at night, when female worms crawl out onto the perianal skin to lay eggs (2). This is typically the live worm seen by patients in the perianal region. Examination of the perineum may reveal secondary bacterial infection of perianal excoriated skin. On occasion, dead parasites or eggs deposited in ectopic sites may lead to the formation of granulomas or abscesses (23). For diagnosis, clear cellulose tape may be placed against the perianal skin, lifted off, and then applied, adhesive side down, to a glass slide and viewed under a microscope to identify the characteristic eggs. Family members and other close contacts should be examined and, if necessary, treated.

ED MANAGEMENT

Pharmacologic therapy of GI parasitic disease is outlined in Table 193.3.

TABLE 193.3
Treatment of Gastrointestinal Parasitic Infections

Drug	Adult Dosage	Pediatric Dosage
	Amebiasis (Entamoeba Histolytical): Asymptomatic	
Drugs of Choice:		
1. Iodoquinol	650 mg PO tid × 20 d	30–40 mg/kg/d (max 2 g) PO in 3 doses × 20 d
2. Paromomycin	25–35 mg/kg/d PO in 3 doses × 7 d	25–35 mg/kg/d PO in 3 doses × 7 d
3. Diloxanide furoate	500 mg PO tid × 10 d	20 mg/kg/d PO in 3 doses × 10 d
	Amebiasis (Entamoeba Histolytical): Mild to Moderate Intestinal Disease	
Drugs of Choice:		
1. Metronidazole	500–750 mg PO tid × 7–10 d	35–50 mg/kg/d PO in 3 doses × 7–10 d
2. Tinidazole	2 g PO daily × 3 d	> or equal to 3 yrs: 50 mg/kg/d (max 2 g) PO × 3 d
Either followed by:		
a. Iodoquinol	650 mg PO tid × 20 d	30–40 mg/kg/d (max 2 g) PO in 3 doses × 20 d
b. Paromomycin	25–35 mg/kg/d PO in 3 doses × 7 d	35–50 mg/kg/d PO in 3 doses × 7 d
	Amebiasis (Entamoeba Histolytical): Severe Intestinal Disease and Extraintestinal Disease	
Drugs of Choice:		
1. Metronidazole	750 mg PO tid × 7–10 d	35–50 mg/kg/d PO in 3 doses × 7–10 d
2. Tinidazole	2 g PO daily × 3 d	> or equal to 3 yrs: 50 mg/kg/d (max 2 g) PO × 3 d
Either followed by:		
a. Iodoquinol	650 mg PO tid × 20 d	30–40 mg/kg/d (max 2 g) PO in 3 doses × 20 d
b. Paromomycin	25–35 mg/kg/d PO in 3 doses × 7 d	25–35 mg/kg/d PO in 3 doses × 7 d
	Ascariasis (Ascaris Lumbricoides, Roundworm)	
Drugs of Choice:		
1. Albendazole	400 mg PO × 1 dose	400 mg PO × 1 dose
2. Mebendazole	100 mg PO bid × 3 d or 500 mg PO × 1 dose	100 mg PO bid × 3 d or 500 mg PO × 1 dose
3. Ivermectin	150–200 µg/kg PO × 1 dose	150–200 µg/kg PO × 1 dose
	Enterobius Vermicularis (Pinworm)	
Drug of Choice:		
1. Pyrantel pamoate	11 mg/kg PO × 1 dose (max 1 g); repeat in 2 wks	11 mg/kg PO × 1 dose (max 1 g); repeat in 2 wks
2. Mebendazole	100 mg PO once; repeat in 2 wks	100 mg PO once; repeat in 2 wks
3. Albendazole	400 mg PO once; repeat in 2 wks	400 mg PO once; repeat in 2 wks
	Giardiasis (Giardia Lamblia)	
Drug of Choice:		
Metronidazole	250 mg PO tid × 5–7 d	15 mg/kg/d PO in 3 doses × 5–7 d
Alternatives:		
1. Tinidazole	2 g PO × 1 dose	50 mg/kg PO × 1 dose (max 2 g)
2. Nitazoxanide	500 mg PO bid × 3 d	1–3 yrs: 100 mg PO bid × 3 d 4–11 yrs: 200 mg PO bid × 3 d >12 yrs: 500 mg PO bid × 3 d
	Hookworm Infection (Ancylostoma Doudenale, Necator Americanus)	
Drugs of Choice:		
1. Albendazole	400 mg PO × 1 dose	400 mg PO × 1 dose
2. Mebendazole	100 mg PO bid × 3 d or 500 mg PO × 1 dose	100 mg PO bid × 3 d or 500 mg PO × 1 dose
3. Pyrantel pamoate	11 mg/kg (max 1 g) PO × 3 d	11 mg/kg (max 1 g) PO × 3 d
	Strongyloidiasis (Strongyloides Stercoralis)	
Drug of Choice:		
Ivermectin	200 µg/kg/d PO × 2 d	200 µg/kg/d PO × 2 d
Alternative:		
Albendazole	400 mg PO bid × 7 d	400 mg PO bid × 7 d
	Trichuriasis (Trichuris Trichiura, Whipworm)	
Drug of Choice:		
Mebendazole	100 mg PO bid × 3 d or 500 mg × 1 dose	100 mg PO bid × 3 d or 500 mg × 1 dose
Alternatives:		
1. Albendazole	400 mg PO daily × 3 d	400 mg PO daily × 3 d
2. Ivermectin	200 µg/kg PO daily × 3 d	200 µg/kg/d PO × 3 d

Adapted from Drugs for parasitic infections. *Med Lett Drugs Ther.* 2007;5(suppl).

DISPOSITION

Many GI parasitic illnesses can be treated with the appropriate antiparasitic agents on an outpatient basis. However, there may be specific indications for inpatient treatment, depending on the causative organism, extent of disease, concomitant medical conditions (immunocompromised patients, etc.), and the reliability of compliance with treatment and adequate follow-up.

Indications for inpatient treatment and potential complications:

- Giardia infection: abnormal electrolytes secondary to excessive diarrhea may require hospitalization.
- *E. histolytica* infection: fulminant rectocolitis, massive GI bleeding, perforation, peritonitis, toxic megacolon, and amebic liver abscess are potential complications.
- *Cryptosporidium* infection: severe diarrhea, especially in immunocompromised patients.
- *A. lumbricoides* infection: intestinal obstruction that requires surgery, especially in the pediatric population.
- *S. stercoralis* infection: hyperinfection syndrome may be fatal in the immunocompromised patient.
- *Necator* and *Ancylostoma* infections: severe hypochromic microcytic anemia in patients with heavy worm burdens.
- *T. trichiura* infection: severe anemia or rectal prolapse.
- *E. vermicularis:* rarely if ever requires inpatient care.

Cysticercosis

Parasitic disease may present with CNS pathology and requires the emergency physician to have a basic understanding of the life cycle of the organisms involved to diagnose and treat the infection.

Protozoal infestations such as malaria may present with neurologic manifestations. Falciparum malaria can cause sludging of parasitized red cells in brain capillaries, resulting in severe CNS dysfunction, which can progress to coma and death. Early recognition and treatment are essential to prevent this outcome.

Helminthic CNS disease is caused primarily by two tapeworms: *Taenia solium* (pork tapeworm) and *Echinococcus granulosus. T. solium,* an intestinal parasite in humans, can invade other tissues in

its larval form, causing cysticercosis. Although 60% of reported cases of cysticercosis involve the brain, it is believed that muscular and subcutaneous encystment is more common (24). Humans may acquire the infestation by eating cured or undercooked pork meat that has been infected with the larvae of *T. solium* (24). In addition, infection may be acquired through the fecal–oral route by consuming contaminated food, such as raw vegetables, or water (25). Cysts formed in the brain (i.e., neurocysticercosis) can cause seizures or produce symptoms through mass effect (2). Worldwide and in the United States, cysticercosis is the most common parasitic disease of the CNS (25). Immigrants from endemic areas, such as Mexico and Central America, account for the vast majority of cases in the United States. Cysticercosis is most prevalent in communities where there is close contact between humans and pigs, and where hygiene is poor (25). *E. granulosus* also forms cysts in the CNS that can mimic neoplastic disease by causing compression effects or seizures.

CLINICAL PRESENTATION

Although *T. solium* is the most common parasitosis of the human CNS, it is symptomatic in only 50% of patients (24). Patients with cysticercosis of the brain may present with focal neurologic findings or impaired sensorium. The clinical features depend primarily on the location of the cyst. The cyst may be located in the meninges, brain parenchyma, or ventricles. The common presenting features include:

- seizures (most prevalent)
- adult-onset seizures in the Third World are most often caused by neurocysticercosis (26)
- focal neurologic deficits
- increased intracranial pressure
- obstructive hydrocephalus
- stroke
- status epilepticus and mechanical hydrocephalus (most frequent causes of death)

ED EVALUATION AND MANAGEMENT

The information obtained from laboratory examination is often limited. A mild peripheral leukocytosis and eosinophilia may be seen. Cerebrospinal fluid (CSF) findings suggestive of cysticercal arachnoiditis include an elevated protein level, eosinophilia, and a predominantly lymphocytic pleocytosis. Several immunologic tests of the serum and CSF have been developed to aid in the diagnosis of cysticercosis (25). Microscopic examination of stool preparations may reveal typical eggs, proglottids (gravid uterus segments), or scolices, which are the heads of the worm. Although the patient with neurocysticercosis may no longer have a tapeworm at the time the diagnosis is made, stools of both the patient and family members should be examined for several days (25). Serologic diagnosis is necessary to confirm *E. granulosus* infection.

Laboratory personnel should be consulted to determine the most appropriate procedures for collecting and handling specimens. The laboratory should be informed of the patient's clinical diagnosis to assist in sample analysis. Consultation with an infectious disease expert may be helpful if the clinician is unfamiliar with the potential manifestations of a particular disease.

Computed tomography (CT) scanning of the head may show both calcified and noncalcified cysts (20,25). Contrast-enhanced CT scanning may demonstrate ring-enhancing lesions in both cysticercosis and echinococcal cyst disease. Magnetic resonance imaging (MRI) has been shown to be more sensitive than CT scan for the detection of active neurocysticercosis, because of the superior ability of MRI to image cysts in the brainstem, subarachnoid space, and ventricles. CT, however, is a better modality for imaging inactive, calcified cysts (20).

Treatment of parasitic CNS disease may involve medical or surgical interventions and depends on the clinical signs and symptoms, the presence of active noncalcified or inactive calcified cysts, and the occurrence of complications. In addition to symptomatic treatment, options for the treatment of neurocysticercosis include anticysticercal drugs, corticosteroids, CSF shunting, and surgical cyst removal (25). Most parasitic infections in the active phase with viable cysts are readily treated with safe and

effective agents. Patients can commonly be treated as outpatients, with appropriate follow-up.

If active neurocysticercosis is suspected, praziquantel (50 mg/kg/d in three divided doses for 15 days) or albendazole (400 mg two times a day for 8 to 30 days) should be initiated (10). Albendazole has shown to be superior to praziquantel in reducing the number of live cysts and in clinically relevant outcomes (27). Corticosteroids should be given for 2 to 3 days before and during drug therapy to suppress the inflammatory response induced by destruction and death of the live cysts (10). Albendazole (400 mg two times a day for 28 days) has been used to treat echinococcal cysts. Surgical removal of cysts remains the most effective treatment, especially when obstructive hydrocephalus is a complicating factor (14). Patients who present with inactive disease (e.g., seizures secondary to parasitic calcifications) are not candidates for treatment with antihelminthic agents. Seizures are treated no differently than seizures from other causes. Neurologic or neurosurgical consultation is appropriate for these patients.

DISPOSITION

Most patients with cysticercosis will either remain asymptomatic without treatment or will be able to receive antihelminthic treatment as an outpatient. However, the clinician should be aware of the need for inpatient treatment in patients who present with signs of severe neurocysticercosis infection; patients with status epilepticus, mechanical hydrocephalus, or stroke require inpatient care and definitive neurosurgery.

CRITICAL INTERVENTIONS

- Diagnose malaria using a thin Giemsa-stained peripheral blood smear to demonstrate intracellular forms of the parasite. Repeat negative blood films every 12 to 24 hours to obtain three negative sets if diagnosis is strongly suspected.
- Diagnose infestation with the pinworm E. vermicularis using clear cellulose tape placed against the perianal skin, lifted off, and then

applied (adhesive side down) to a glass slide and viewed under a microscope to identify the characteristic eggs.
- Diagnose cysticercosis with CT and/or brain MRI in addition to serologic testing.

Common Pitfalls

- Failure to consider parasitic disease as a potential etiology for a variety of systemic, GI, CNS, and skin complaints. Parasitic disease should be considered in any patient presenting from an endemic area or with a travel history to an endemic area.
- Failure to consider parasitic infestation in travelers months after their return.
- Failure to consult reference textbooks and current therapeutic guidelines concerning the appropriate diagnosis and treatment for these diseases.

CHAPTER 194

Blood and Body Fluid Exposures in the Healthcare Worker

Samuel O. Clarke and Peter E. Sokolove

Despite the introduction of a safe and effective vaccine in 1982, hepatitis B (HBV) remains a potential occupational hazard among healthcare workers. Between 804,000 and 1.4 million Americans are infected with HBV, the majority of whom are unaware of their infection status (1). As of 2011, the majority of healthcare providers in the United States have received vaccination against Hepatitis B, and between 93% to 95% are thought to be protected based on vaccination efficacy data (2). Though the incidence of hepatitis B infection in 2007 has declined by 82% since 1990, unvaccinated healthcare workers remain at significant risk (1,3). HBV vaccination plays the central role in prevention of disease among healthcare workers and has reduced the number of HBV cases, hospitalizations, and deaths by about 80% since prevaccine levels (4).

Although the acquired immunodeficiency syndrome (AIDS) accounts for a much smaller number of cases than does hepatitis B, it often causes more concern among healthcare workers. It is estimated that over 380,000 needle stick exposures to blood occur annually among US healthcare workers, equating to roughly 1 in 10 healthcare workers having a significant exposure each year (5). A recent study of patients with penetrating trauma presenting to an urban emergency department (ED) found an incidence of seropositivity for HIV, HBV, or HCV of more than 9%, and the

majority of cases were in patients who were unaware of their seropositive status (6). Despite these risks, as of December 2010, there were only 57 confirmed and 143 possible occupational human immunodeficiency virus (HIV) infections among healthcare workers in the United States (7). Emergency physicians must be well versed in the management of HIV exposures, as both healthcare workers and non-healthcare workers visit the ED for exposure management.

Previously known as non-A non-B hepatitis, hepatitis C virus (HCV) is now the most common chronic blood-borne infection in the United States. Between 3.2 and 5.4 million Americans are chronically infected with this virus, with about 20,000 new infections each year (8,9). Though the overall prevalence of HCV in healthcare workers is similar to that of the general population (1% to 2%), ED personnel are at high risk of exposure. In a recent study from a Midwestern ED, the prevalence of HCV infection among patients was 4% (10). In 2005, about 8% of persons with new HCV infections in the United States reported occupational exposure to blood (8).

CLINICAL PRESENTATION

Healthcare workers frequently present to the ED after exposure to material potentially infected with HBV, HCV, or HIV. First, the exposure must be assessed. Although blood is the single most important source of infection, other fluids may also transmit disease. Semen or vaginal secretions; cerebrospinal, synovial, pleural, peritoneal, pericardial, or amniotic fluid; and tissue are capable of transmitting HIV, HBV, and probably HCV. Unless blood is visible in them, feces, nasal secretions, sputum, sweat, and tears have not been identified as vehicles of transmission for HBV, HCV, or HIV infection. Transmission occurs most effectively through direct percutaneous exposure (e.g., needlestick); although far less likely, exposure through mucous membranes or open skin lesions can also result in HBV, HCV, and HIV transmission. Casual contact, airborne, and fecal–oral transmission have not been documented (8). The factors associated with the greatest risk of HIV transmission after percutaneous exposure are: deeply penetrating injury, presence of visible blood on the injuring object, prior placement of the object in

a patient's vein or artery, and end-stage AIDS in the source patient (11).

ED EVALUATION

An initial evaluation should be made to assess the risk of disease transmission. Information about the injury should be gathered, including the infectious material, instrument procedure performed, depth of penetration, and volume of blood transferred. The source person should be evaluated for HIV and hepatitis risk factors, clinical signs of disease, previous HIV therapy, and viral load or CD4 count, if known.

The healthcare worker should be evaluated for his or her medical history and immunization status for hepatitis B and tetanus. The source blood should be tested for hepatitis B surface antigen (HBsAg), HCV, and HIV antibodies. If the source is found to be positive for HBsAg, the source should also then be tested for hepatitis B e antigen (HBeAg) and direct measurement of viral DNA, as some patients do no exhibit e antigen despite high viral burden (2).

The exposed healthcare worker should be tested for hepatitis B surface antibody (HBsAb), HCV, and HIV. Baseline complete blood count, basic metabolic profile, and liver function tests should be obtained along with urine pregnancy screening, as appropriate (12,13).

The circumstance of testing source patients who are unable or unwilling to consent to testing deserves special mention. There is considerable heterogeneity in state laws regarding unconsented testing, with some states (e.g., Arizona, Maine, New Mexico, Oregon) requiring a court order for any unconsented test, and others (e.g., California, South Carolina, Rhode Island) allowing unconsented testing even in patients with full capacity who refuse voluntary testing (14). Emergency physicians should be familiar with and adhere to laws governing unconsented testing for the state in which they practice. Every attempt should be made to explain the risks and benefits of testing to source patients, as well as the possibility of unconsented testing in certain circumstances.

KEY TESTING

- Source patient: Hepatitis B surface antigen (HBsAg), HCV antibody, HIV antibody, HBeAg, and Hepatitis B viral DNA if source patient is found to be positive for HBsAg
- Exposed worker: Hepatitis B surface antibody (HBsAb)*, HCV antibody, HIV antibody, complete blood count, basic metabolic profile, liver function tests, urine pregnancy

*Unless worker known to be immune against Hepatitis B

ED MANAGEMENT

Hepatitis B Virus Exposure

Two types of products are available for the management of the exposed healthcare worker. Hepatitis B immune globulin (HBIG), derived from plasma containing high titers of antibody to HBsAg, confers passive immunity. Side effects are minimal, and there is no evidence of HBV or HIV transmission with this product. For postexposure prophylaxis, the dose is 0.06 mL/kg intramuscularly. It should be administered within 72 hours of exposure (preferably within 24 hours) and is probably not useful beyond 7 days. The wholesale cost of HBIG in 2010 ranged from $640 to $804 (15).

Hepatitis B vaccine is available for active immunization. It is a recombinant vaccine that is very safe, even in pregnancy. For postexposure prophylaxis of nonvaccinated individuals, 1 mL of vaccine is administered intramuscularly in the deltoid within 7 days of exposure and repeated at 1 month and 6 months. Because about 10% of adults will not initially achieve the recommended antibody titer after this series, antibody levels should be checked 4 to 6 weeks after the series is completed. Nonresponders should be given a second three-dose series of vaccine and retested for antibody levels (16). For healthcare workers who achieve a level of at least 10 mIU/mL, the vaccine is essentially 100% effective in preventing subsequent HBV infection. The wholesale price in 2013 for HBV vaccine ranges from $52.50 to $61.22 per dose (17).

Whether to administer HBIG, HBV vaccine, both, or neither is based on the HBsAg status of the source person and the vaccination status of the exposed healthcare worker (Fig. 194.1) (16). A source person can transmit HBV if HBsAg is present, but the degree of infectivity is best correlated with HBeAg positivity. The risk of seroconversion after a percutaneous injury ranges from 23% to 62% in unvaccinated persons and depends on the HBeAg status of the source (18). Overall, about 25% of those infected with HBV develop acute hepatitis, and 6% to 10% develop chronic infection. These patients are at increased risk of cirrhosis and hepatocellular carcinoma.

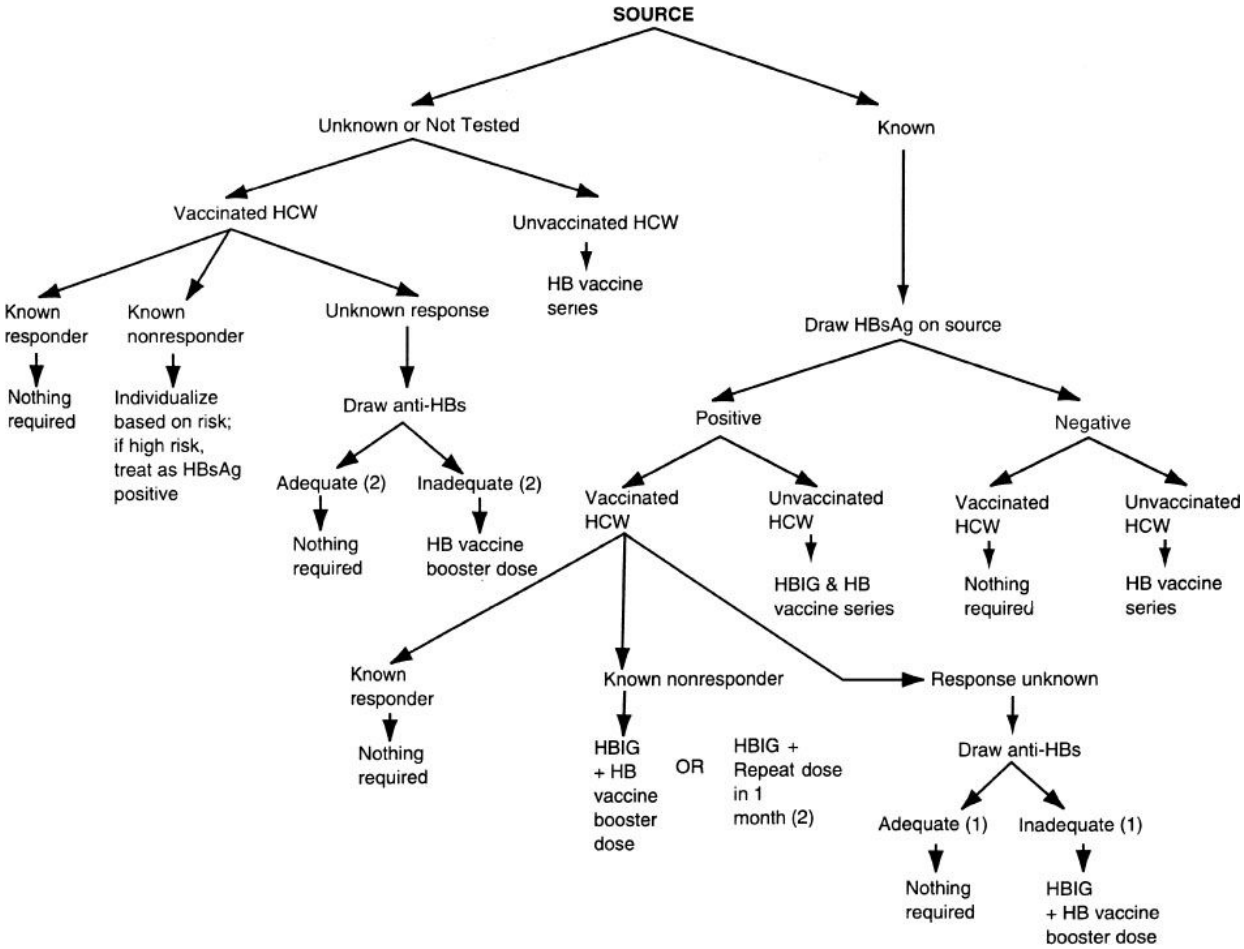

FIGURE 194.1 Hepatitis B exposure algorithm. **1:** Adequate antibody ≥10 mIU/mL. **2:** Preferred for those who have failed to respond to a second three-dose series of vaccine. (Adapted from CDC. Updated U.S. Public Health Service guidelines for the management of

occupational exposures to HBV, HCV, and HIV and recommendations for postexposure prophylaxis. *MMWR Morb Mortal Wkly Rep.* 2001;50(RR-11):22.)

Hepatitis C Virus Exposure

There are currently no agents available for managing exposure of the healthcare worker to HCV (16). Immune globulin is not useful for postexposure prophylaxis of HCV for a number of reasons. In contrast to HBsAb, HCV antibody is only a marker antibody, not a neutralizing antibody. Even if a neutralizing antibody did exist among the donor population, immune globulin is derived from plasma donors that are excluded from donation if they test positive for HCV. Finally, HCV mutates rapidly, and new variants may be unaffected by neutralizing antibodies.

There is currently no vaccine against HCV, as this virus demonstrates great genetic heterogeneity and a high mutation rate. The combination of pegylated interferon and ribavirin is commonly used successfully to treat patients with chronic hepatitis due to HCV (19). Unfortunately, there is currently no postexposure prophylaxis available for HCV, though recently marketed HCV protease inhibitors may play a future role (2). Thus, the use of standard precautions and medical devices with safety features is crucial for preventing HCV exposures (18).

The average risk of acquiring HCV infection after percutaneous exposure is 1.8% and ranges from 0% to 7% (16,18). This risk is similar to the risk of HBV transmission after percutaneous exposure to HBsAg-negative blood. Of those who acquire HCV infection, 55% to 85% will remain infected. The risk of developing cirrhosis ranges between 5% to 25% over periods of 25 to 30 years, and the risk of developing hepatocellular carcinoma is between 1% and 3% per year (19).

Human Immunodeficiency Virus Exposure

ED management of potential exposure to HIV materials consists of serologic testing of the exposed healthcare worker and exposure

source, counseling the healthcare worker on the risk for infection, and consideration of postexposure prophylaxis. Though the use of antiviral agents to prevent HIV seroconversion in exposed healthcare workers was once considered highly controversial, an accumulation of evidence supports the use of certain drugs in many cases. The theoretical basis for postexposure prophylaxis is that antiretroviral agents may prevent or limit the replication of HIV in dendritic cells or regional lymph nodes, which appear to be the initial targets and route of spread of HIV (16). Animal studies as well as studies of prophylactic administration of antiretroviral medications to HIV-infected mothers have demonstrated a significant protective effect from initiation of prophylactic antiretroviral treatment (16). Though transmission during pregnancy is different from percutaneous exposure, these data clearly demonstrate that antiviral agents can be used to prevent blood-borne infection in an HIV-negative individual. The most compelling evidence of postexposure prophylaxis efficacy, however, was a multinational case-control study, performed by the CDC (11). In this study of healthcare workers who had HIV exposures, mostly as a result of hollow-bore needlesticks, the risk for HIV infection was reduced by 81% if AZT was given after exposure. These data prompted the Public Health Service in 1998 to first recommend postexposure prophylaxis for healthcare workers exposed to HIV (16). These recommendations were updated and reaffirmed in 2001 and 2005, and a new revision of the CDC guidelines is currently underway (16,20).

Though AZT is the only drug with clinical data supporting its use for HIV postexposure prophylaxis in humans, multidrug regimens are now employed because of concerns about AZT-resistant strains of HIV and a demonstrated synergistic effect of certain antiviral agents in the treatment of patients for AIDS.

There are now six classes of medications that can be used for HIV postexposure prophylaxis. Most commonly used are the nucleoside reverse transcriptase inhibitors and protease inhibitors. Other choices include nonnucleoside reverse transcriptase inhibitors, *nucleotide* reverse transcriptase inhibitors, integrase inhibitors, and fusion inhibitors (2). Each of these medications has associated risks,

including various side effects, drug interactions, and oncogenic or teratogenic potential. The drug regimen chosen depends upon the exposure severity, the suspicion for antiviral resistance in the source, and the exposed patient's medical history. Expert consultation should be sought to assist with drug selection whenever source resistance is suspected (20). All of the regimens recommend a 28-day course of treatment for a known HIV-positive source or high-risk exposure (2).

When determining whether to initiate postexposure prophylaxis and which agents to choose, the physician must consider a number of factors. The route and severity of exposure help determine the risk of seroconversion and thus the potential benefit of postexposure prophylaxis. If the skin integrity is compromised or if mucous membranes are exposed, transmission is unlikely but can occur. The risk of transmission after a mucous membrane exposure to blood is about 0.1% (1 in 1,000). The risk of transmission can be higher if a large volume of blood is involved or if prolonged contact occurs. The average risk for HIV transmission after percutaneous blood exposure is about 0.3% (1 in 300) but depends on the severity of the exposure (16). Table 194.1 lists the risk factors for HIV transmission after percutaneous blood exposure, as reported in the previously described CDC case-control study (11).

TABLE 194.1
Risk Factors for HIV Transmission after Percutaneous Blood Exposure

Risk Factor	Odds Ratio	95% CI
Deep injury	15	6–41
Blood visible on device	6.2	2.2–21
Procedure with needle placed directly into artery or vein	4.3	1.7–12
Terminal AIDS in source patient	5.6	2–16
Postexposure zidovudine	0.19	0.06–0.52

Adapted from Cardo DM, Culver DH, Ciesielski CA, et al. A case-control study of HIV seroconversion in health care workers after percutaneous exposure. *N Engl J Med.* 1997;337:1487.

The HIV status of the source person is also important when assessing the risk of transmission and choice of antiviral agents. If the source person is currently HIV-negative and has not had a recent retroviral-like illness (symptoms similar to those of acute mononucleosis), postexposure prophylaxis is not indicated. For HIV-positive source persons, the degree of infectivity is related to the patient's viral load. HIV-positive source patients can be categorized as either lower risk (class 1) or higher risk (class 2). Class 1 patients include those with asymptomatic HIV infection and a viral load of $<$1,500 RNA copies/mL. Class 2 patients include those with either symptomatic HIV, AIDS, acute seroconversion, or a viral load above 1,500 RNA copies/mL (20).

Based upon the severity of an exposure and the source HIV status (class 1 or 2), either a basic (two-drug) or an expanded ($\geq$three-drug) regimen is recommended by the CDC (20). The most commonly used *basic regimen* combines AZT and lamivudine (3TC). Other recommended basic regimens are AZT plus emtricitabine (FTC); tenofovir (TDF) plus 3TC; and TDF plus FTC. Alternative basic regimens, to be considered in special circumstances, include 3TC plus stavudine (d4 T); FTC plus d4 T. The preferred *expanded regimen,* used for higher-risk exposures, is made by adding lopinavir/ritonavir (a combination of two protease inhibitors) to the basic regimen. Alternative expanded regimens, to be considered in special circumstances, can be made by substituting other medications in place of lopinavir/ritonavir. The choices include atazanavir (ATV) $\pm$ ritonavir (RTV); fosamprenavir (FOSAPV) $\pm$ RTV; indinavir (IDV) $\pm$ RTV; saquinavir (SQV) $\pm$ RTV, or efavirenz (EFV). Antiviral agents that are generally *not* recommended for postexposure prophylaxis include nevirapine (NVP), delavirdine (DLV), abacavir (ABC), and zalcitabine (ddC). Finally, the HIV fusion inhibitor enfuvirtide can be considered for postexposure prophylaxis but only with expert consultation (2,20).

For skin and mucous membrane exposures, the postexposure prophylaxis regimen chosen falls into three general categories (Table 194.3). For small volume exposures (few drops of blood) from an HIV class 1 source, a basic regimen (two drugs) should be *considered.*

If either the exposure is of large volume (major blood splash) or the source is HIV class 2, a basic regimen should be *recommended.* In cases where there is both a large volume exposure and an HIV class 2 source, an expanded regimen (at least three drugs) should be recommended (20).

At times, emergency physicians need to make postexposure prophylaxis recommendations to patients who have sustained an exposure from either an unknown source (e.g., needle left on an open counter) or, more commonly, from a known source with unknown HIV status. In such circumstances, the need for HIV postexposure prophylaxis should be decided on a case-by-case basis. In cases of an unknown source, postexposure prophylaxis is generally not recommended, but a two-drug regimen should be considered for exposures occurring in an HIV-likely setting (e.g., exposure to a discarded needle on an AIDS ward). For a source of unknown HIV status, rapid HIV testing can be used to quickly determine the need for postexposure prophylaxis (16). Postexposure prophylaxis can be withheld pending HIV test results but only if a 1-hour rapid HIV test is available. Although this test is now used in more than half of academic EDs, it is not available in all practice settings (21). In such circumstances, the decision to start postexposure prophylaxis should be made via discussion of risks and benefits with the exposed person, based upon the source person's likelihood of HIV infection. Postexposure prophylaxis can always be initiated and then stopped or modified once the source person's HIV status has been determined (20).

Animal studies have demonstrated that the efficacy of postexposure prophylaxis is related to the time from exposure to initiation of treatment. Potential HIV exposures should be treated as true emergencies, and postexposure prophylaxis should be initiated within 2 hours of exposure if possible (22). It is unclear how long after exposure treatment can be initiated and still be effective, but animal data suggest that some benefits may persist up to 36 hours (22).

Once HIV postexposure prophylaxis has been initiated, medications are optimally administered for a 4-week course. This can

be challenging, because adverse symptoms are very common, causing about one-third of healthcare workers to discontinue therapy. Thus, patients should be prescribed medications (e.g., antiemetics, antidiarrheal agents) to mitigate the side effects of the selected treatment regimen. Alternative basic regimens are becoming increasingly popular due to the belief that their more favorable side effect profiles result in better rates of compliance (22,23). The New York State Department of Health AIDS institute currently recommends a three-drug regimen of tenofovir, emtricitabine, and raltegravir for initial postexposure prophylaxis (22). All patients sustaining an HIV exposure should be referred for follow-up and re-evaluation, even if postexposure prophylaxis was not initiated, to allow for counseling, postexposure testing, and medical evaluation. When initiating postexposure prophylaxis, follow-up should probably occur within 72 hours. Prompt follow-up is most important if new information about the source becomes available (e.g., viral load, medication resistance), as this may warrant a change in medication regimen (20).

Summary of Acute Management

Acute management includes thorough washing of the exposed area with soap and warm water or flushing of mucous membranes. As with all wounds, the need for tetanus toxoid administration should be considered. HBIG or hepatitis B vaccine or both should be administered as indicated (Fig. 194.1). HIV postexposure prophylaxis should be recommended based on the exposure type and the source HIV status (see Tables 194.2 and 194.3). The healthcare worker should be counseled regarding the risks of HBV, HCV, and HIV infection and modifications of behavior (e.g., abstinence or condom use) to prevent secondary infection of others.

TABLE 194.2
Recommended HIV Postexposure Prophylaxis for Percutaneous Injuries

Infection Status of Source		
Exposure Type	HIV-positive Class 1[a]	HIV-positive Class 2[a]
Less severe[b]	Recommend basic 2-drug PEP	Recommend expanded ≥3-drug PEP
More severe[c]	Recommend expanded 3-drug PEP	Recommend expanded ≥3-drug PEP

[a]HIV-positive, Class 1—asymptomatic HIV infection or known low viral load (e.g., <1,500 RNA copies/mL). HIV-positive, Class 2—symptomatic HIV infection, AIDS, acute seroconversion, or known high viral load. If drug resistance is a concern, obtain expert consultation. Initiation of postexposure prophylaxis should not be delayed pending expert consultation and, because expert consultation alone cannot substitute for face-to-face counseling, resources should be available to provide immediate evaluation and follow-up care for all exposures.
[b]Less severe (e.g., solid needle or superficial injury).
[c]More severe (e.g., large-bore hollow needle, deep puncture, visible blood on device, or needle used in patient's artery or vein).
Adapted from CDC. Updated U.S. Public Health Service Guidelines for the management of occupational exposures to HIV and recommendations for postexposure prophylaxis. *MMWR Morb Mortal Wkly Rep.* 2005;54(RR-9):3.

TABLE 194.3
Recommended HIV Postexposure Prophylaxis for Mucous Membrane Exposures and Non-Intact Skin Exposures[a]

Infection Status of Source		
Exposure Type	HIV-positive Class 1[b]	HIV-positive Class 2[b]
Small volume[c]	Consider basic 2-drug PEP[d]	Recommend basic 2-drug PEP
Large volume[e]	Recommend basic 2-drug PEP	Recommend expanded ≥3-drug PEP

[a]For skin exposures, follow-up is indicated only if there is evidence of compromised skin integrity (e.g., dermatitis, abrasion, or open wound).
[b]HIV-positive, Class 1—asymptomatic HIV infection or known low viral load (e.g., <1,500 RNA copies/mL). HIV-positive, Class 2—symptomatic HIV infection, AIDS, acute seroconversion, or known high viral load. If drug resistance is a concern, obtain expert consultation. Initiation of postexposure prophylaxis should not be delayed pending expert consultation and, because expert consultation alone cannot substitute for face-to-face counseling, resources should be available to provide immediate evaluation and follow-up care for all exposures.
[c]Small volume (i.e., a few drops).
[d]The designation, "consider PEP" indicates that postexposure prophylaxis (PEP) is optional and should be based on an individualized decision between the exposed person and the treating clinician.
[e]Large volume (i.e., major blood splash).
Adapted from CDC. Updated U.S. Public Health Service Guidelines for the management of occupational exposures to HBV, HCV, and HIV and recommendations for postexposure prophylaxis. *MMWR Morb Mortal Wkly Rep.* 2005;54(RR-9):3.

CRITICAL INTERVENTIONS

- Initiate therapy for post-HIV exposure within 2 hours.
- Administer postexposure prophylaxis HBIG within 72 hours of exposure (preferably within 24 hours) and hepatitis B vaccine within 7 days of exposure and repeated at 1 month and 6 months to unvaccinated healthcare workers who are exposed to an HbsAg-positive source.

Common Pitfalls

- A common error in the management of healthcare worker exposures is to provide either unnecessary or inadequate treatment. Unnecessary treatment usually results from an overestimation of the infectious potential of an exposure, such as providing three-drug antiretroviral therapy for a blood splash onto intact skin. Undertreatment can occur if the treating physician is unaware of the benefit of postexposure prophylaxis or if treatment for HIV exposure is delayed. These pitfalls can be avoided by applying a standardized protocol, such as the algorithms presented here. In uncertain or complex cases, consultation with an employee health service or an infectious disease specialist is advised.

CHAPTER 195

Food Poisoning

Marc C. Restuccia

The Centers for Disease Control (CDC) estimates that roughly 1 in 6 Americans (48 million) become ill, 128,000 are hospitalized and 3,000 die of foodborne illnesses each year (1). This number is an improvement over previous estimates published by CDC of 76 million made ill, 323,000 hospitalized and 5,000 annual deaths (2). Despite these improvements, foodborne illness remains a serious public health problem. Even as advances have been made in decreasing the incidence of certain foodborne illnesses, the incidence of others has either remained the same or worsened somewhat (3). In 1996, the CDC established the Foodborne Diseases Active Surveillance Network, known as FoodNet. This easily accessible resource tracks foodborne illnesses as well as monitors efforts to enhance food safety.

Food can be contaminated during all stages of production. “Modern” industrial sized farms and centralized; worldwide distribution systems create opportunities for amplification of any breakdown in food safety systems. Food can be contaminated with bacteria, viruses, parasites, toxins, and the relatively newly described prions.

For most people suffering from foodborne illness, it is a self-limited process with nausea, vomiting, abdominal pain, and diarrhea. In other patients, however, it can present with neurologic symptoms, hepatic failure, or renal failure. As in many disease processes, the young, the old, and the immunocompromised are at greater risk for significant sequelae. The clinician must also be wary of other, often more serious illnesses, which can be mistaken for food poisoning.

Individual cases of foodborne illness are virtually impossible to diagnose with any certainty, overlapping with nonfoodborne gastrointestinal infections. The diagnosis is most typically entertained and confirmed when multiple persons become ill and the etiology can be traced to a specific event and/or food.

CLINICAL PRESENTATION

Alteration of normal gastrointestinal tract function is the most typical presentation for a patient with a foodborne illness. Nausea, vomiting, diarrhea, abdominal pain, and fever are the most common complaints. However exceptions exist; botulism, caused by the botulinum toxin, classically seen in infants consuming raw honey (4), presents with a progressive paralysis. Other manifestations of foodborne illness can include neurologic symptoms (seen with Scombroid and Ciguatera fish poisoning as well as mushrooms) as well as systemic illness including fever, weakness, jaundice, and arthritis (seen with Salmonella, Toxoplasma, and Trichinella poisoning) (5). Abdominal pain is a frequent complaint in patients with a foodborne illness and it can be difficult to differentiate the cause from other conditions such as appendicitis.

Diarrhea can be watery or bloody. This may be helpful in narrowing down the diagnostic possibilities. Although the presence of watery diarrhea is fairly nonspecific, bloody diarrhea implies an enteroinvasive diarrhea, with the most common cause being *Escherichia coli* 0157-H7 and Salmonella. Campylobacter less commonly causes bloody diarrhea (6).

With progression of the illness, dehydration may develop. Thirst, dry mucous membranes and eventually tachycardia with hypotension can be seen, especially in acutely ill children or the elderly. Altered mental status more commonly affects in the young and elderly. Table 195.1 lists the major manifestations associated with the more common pathogenic organisms.

TABLE 195.1
Bacterial Causes of Food Poisoning

Agent	Incubation	Duration	Common Food Sources	Manifestations	Treatment
Bacillus anthracis[a]	2 d to weeks	Weeks	Insufficiently cooked and contaminated meat	Nausea, vomiting, malaise, bloody diarrhea Acute abdominal pain	Cipro, PCN, or Doxycycline
Bacillus cereus Vomiting	3 hrs	12 hrs	Spices and grains such as rice, especially	Fried rice ingestion	Supportive
Diarrhea (Toxin)	10 hrs	36 hrs	If inadequate refrigeration	(–) fecal leukocytes	
Campylobacter jejuni	3 d	4 d	Unpasteurized milk, dairy products	abdominal pain, fever, diarrhea, biphasic illness (+) fecal leukocytes	FQ, AG, macrolides
Clostridium botulinum (toxin)	30 hrs	Variable	Improper home canning, unpasteurized honey	Flu-like symptoms, descending weakness or paralysis, ptosis paralysis, may have no GI symptoms	Supportive (horse serum antitoxin)
Clostridium perfringens	12 hrs	24 hrs	Meat, meat by-products, poultry (cooked but inadequately refrigerated)	Nonbloody diarrhea (–) fecal leukocytes	Supportive
Cryptosporidium	6 d	6 d	Hand-pressed cider, municipal water supplies, public pools	Vomiting, diarrhea, worse if immunocompromised	Supportive
Escherichia coli 0157:H7 (toxin)	48 hrs	1 wks	Raw or undercooked beef fast food restaurants	Copious bloody diarrhea, (+) fecal leukocytes, rarely HUS, renal failure	Supportive
Traveler's diarrhea enterotoxigenic (toxin)	12–72 hrs	24–72 hrs	Raw vegetables, seafood, improperly cooked food from street vendors, hot pepper sauce, tap water	Watery diarrhea, low-grade fever, (–) fecal leukocytes	FQ, Macrolides, may consider anti-motility agents with antibiotics
Enteroinvasive (invasive)	12–72 hrs	24–72 hrs	Similar to above	Severe cramps, malaise initially watery, then bloody diarrhea, (+) fecal leukocytes	Macrolides, TMS
Listeria monocytogenes	1–70 d	Variable	Beef, pork, poultry, cheese (soft, "Mexican style," Swiss), milk, contaminated after pasteurization fruits and vegetables, other dairy products	More severe in pregnancy immunocompromised, usually (+) fever, may have limited GI symptoms	Ampicillin, PCN, AG
Salmonella (invasive)	24 hrs	5 d	Dairy products, poultry, eggs, chocolate, coconut, dried foods	Watery, bloody diarrhea, (+/–) fecal leukocytes, possible, possible bacteremia	Immunocomp. pts. septic pts., Rx with ceftriaxone FQ, chloramphenicol
Shigella (invasive)	1–3 d	5 d	Any food contaminated with fecal material during processing, ice in developing countries	Copious bloody diarrhea, fever, cramps, rarely; DIC, HUS, sepsis, children may have seizures, usually (+) fecal leukocytes	Macrolides, TMS
Staphylococcus aureus (toxin)	4 hrs	20 hrs	Milk and dairy products, ham, potato salad, custards, pastry	Vomiting, cramps, diarrhea, usually no fever	Supportive
Vibrio b Cholerae	24–72 hrs	3–7 d	Profuse, watery diarrhea and vomiting, can lead to death from severe dehydration	Contaminated water, fish, shellfish, street vended food typically Latin America or Asia	Supportive care, rehydr., TCN, DCN, adults, Macrolides, FQ
Parahemolyticus	2–48 hrs	2–5 d	Watery diarrhea, abdominal cramps, nausea, vomiting	Undercooked or raw seafood, such as fish, shellfish	Supportive care, in severe cases, TCN, DCN, ceftriaxone, or cefotaxime
Vulnificus	1–7 d	2–8 d	Vomiting, diarrhea, abdominal pain, bacteremia, wound infections, more common if immunocompromised	Undercooked or raw shellfish, especially oysters, other seafood, open wounds	Supportive care, TCN, DCN, ceftriaxone, or cefotaxime
Yersinia enterocolitica	15–24 hrs	2 wks	Foods contaminated with fecal material during handling (e.g., tofu, bean sprouts, milk, milk products, water supply)	Diarrhea, fever, abdominal pain, vomiting, bloody stools, may be protracted, can lead to appendicitis operations (+) or (–) fecal leukocytes	Antibiotics of value FQ, TMS, AG

[a]FQ, fluoroquinolones; AG, aminoglycosides; HUS, hemolytic uremic syndrome; TMS, trimethoprim-sulfamethoxazole; DIC, disseminated intravascular coagulation; TCN, tetracycline; DCN, doxycycline; PCN, penicillin.

From Diagnosis and management of foodborne illness: A primer from physicians and other health care professionals. *MMWR*, 2004.

DIFFERENTIAL DIAGNOSIS

The diagnosis of foodborne illness is typically made on clinical grounds. The Physical examination, although important in assessing the volume status of the patient, typically does not distinguish the cause of nausea, vomiting, abdominal pain, fever, and/or diarrhea. As is noted in Table 195.1, the incubation period for many of these illnesses is measured in hours, if not days. A history of recent meals,

especially meals where other individuals may have shared foods and time of ingestion may be helpful to determine the source.

Toxin-producing pathogens such as enterotoxigenic *E. coli, Staphylococcus aureus,* and *Vibrio cholerae* often cause profuse watery diarrhea. Symptoms begin within hours of ingesting contaminated foods. By way of contrast, organisms such as *Cryptosporidium cyclospora* and *Giardia* also lead to a watery diarrhea, typically days to weeks after ingestion. Hikers and campers who drink unfiltered or untreated back-country water are at risk of developing painful abdominal cramping, profuse watery diarrhea, and flatulence from *Giardia* infection.

Invasive organisms such as nonenterotoxigenic *E. coli, Campylobacter, Shigella, Yersinia,* and *Vibrio* infect the cells lining the intestinal tract and cause a bloody diarrhea that typically begins within 24 hours of ingestion. The stools of such patients will typically have both occult blood and fecal leukocytes (8). The parasite, *Entamoeba histolytica* can also cause bloody diarrhea. *Clostridium difficile,* which colonizes the human gastrointestinal tract after the normal flora has been suppressed by wide-spectrum antibiotics, releases toxins which lead to a profuse bloody diarrhea. Although not a foodborne illness, with increased use of wide-spectrum antibiotics, it is an increasingly and difficult to treat condition causing diarrhea, abdominal pain, vomiting, and fever.

Viral infections are the leading cause of nausea, vomiting, and diarrhea. Rotavirus is an illness of young children during the winter months. Norovirus, Hepatitis A, and Parvovirus show no seasonal predilection. Typically vomiting is more prominent in viral gastroenteritis and toxin-related foodborne illness than in other types of gastroenteritis resulting from bacterial or parasitic infections. Characteristics of the history that are consistent with a viral etiology include an incubation period of 20 to 60 hours, a duration of 12 to 60 hours and a high frequency of vomiting (9).

Contamination of food with pesticides or other chemicals during growth, harvesting, or processing can also lead to foodborne illnesses (10,11).

Other conditions that must be considered in the differential diagnosis of anyone presenting to the emergency department (ED) with nausea, vomiting, fever, and abdominal pain include biliary tract disease, peptic ulcer disease, coronary artery disease, appendicitis, intussusception, volvulus, diverticulitis, inflammatory bowel disease as well as poisoning by heavy metals, mushrooms, and seafood toxicity.

ED EVALUATION

The history should focus on recent meals, within 24 to 48 hours prior to presentation. Key questions include what was consumed, how it was prepared, how was it stored after preparation, and whether or not anyone else is ill who consumed the same food. The time of onset, nature, and progression of the illness, particularly the character of the diarrhea should be noted. Patients should be asked about travel, especially to regions with a high incidence of foodborne illness such as Mexico. Any recent use of antibiotics should be ascertained. For patients who are hikers or campers, questions about drinking unfiltered or untreated water in the recent past should be sought. Underlying medical conditions, especially those that may lead to immunodeficiency such as diabetes, or malignancies should be determined. Other significant medical conditions such as coronary artery disease should be identified and noted.

The physical examination should focus on the hydration status of the patient and a general physical examination, with particular attention to the abdomen. Serial examinations including vital signs, allow the treating clinician to rapidly identify and deterioration of the patient's condition. Laboratory testing may rarely assist in identifying the cause of a foodborne illness. Routine blood tests are usually not indicated. The CDC does recommend blood testing for patients with bloody diarrhea, weight loss, dehydration, fever, prolonged diarrhea (three or more unformed stools per day for several days), neurologic involvement (such as paresthesias, other weakness or cranial nerve palsies), sudden onset of symptoms, or severe abdominal pain (5). Laboratory testing is also recommended for the young and old and in those patients with comorbid conditions

or immunosuppression. In these cases, a complete blood count, basic metabolic panel (electrolytes, BUN, creatinine, glucose), and a urinalysis are reasonable. Blood cultures have long been recommended for patients suspected of bacteremia, however recent literature calls this into question (12). Patients with significant abdominal pain, suspicious for a surgical etiology should have either a screening upright CXR bedside ultrasound or abdominal CT as indicated on the basis of their presentation. A screening ECG is indicated if any concern is raised about the potential for an acute myocardial infarct presenting with GI symptoms. This is especially true for women and the elderly.

Patients with severe abdominal pain and bloody diarrhea should have their stool checked for fecal leukocytes. *C. difficile* stool toxin assays should be ordered on patients with a history of recent antibiotic use.

Stool cultures are indicated for immunocompromised or febrile patients with bloody diarrhea, presence of fecal leukocytes or severe, protracted illness. Laboratory protocols and procedures can differ between facilities. Many laboratories are limited to testing for *Salmonella, Shigella, and Campylobacter* species. If *Vibrio, Yersinia,* or *E. coli* O157:H7 are suspected, special collection and handling are usually necessary. Consultation with the hospital's microbiology laboratory is important to ensure proper collection and handling of specimens. Stool should be examined for parasites if the patient has a suggestive travel history, is immunocompromised or has persistent diarrhea.

KEY TESTING

- Routine (most patients): Electrolytes, HCG
- Bloody diarrhea: Fecal leukocytes/occult blood
- CBC, consider blood cultures
- Titer for *C. difficile*
- Immunocompromised: CBC, blood cultures
- Surgical abdomen: Upright chest x-ray
- Bedside ultrasound
- Abdominal/pelvic CT scan

- Preoperative laboratories
- Travel: Stool for ova and parasites
- Concern for an MI: ECG
- Bloody stools/Immunocompromised: Stool culture

ED MANAGEMENT

The first priority for any patient presenting to the ED with nausea, vomiting, diarrhea, abdominal pain, and fever is adequate volume resuscitation. In many patients this can be accomplished with oral rehydration. Some patients however will not be able to tolerate oral hydration and will have to be resuscitated intravenously. Fluid boluses if needed to establish an age normal mean blood pressure, followed by maintenance infusions should be initiated. Antiemetics such as ondansetron or metoclopramide may be helpful, especially if oral hydration is being attempted. Anti-diarrheal medications are now accepted as routine therapy for patients with traveler's diarrhea, typically caused by strains of *E. coli.* However, such medications should not be given to patients with bloody diarrhea as it is thought that their use can prolong symptoms or lead to more serious complications.

Antibiotics are indicated in only a small number of foodborne illnesses. Diarrhea due to viruses and most bacteria does not improve more rapidly with antibiotics and can actually worsen. However, antibiotics may be appropriate in patients who are septic, immunosuppressed, the elderly, or have serious comorbid conditions. Table 195.1 contains recommendations for when antibiotics are appropriate therapy.

The CDC requires notification of state and/or local public health departments for certain foodborne illnesses. Prompt notification of the appropriate local department of public health enables authorities to determine the best course of action to limit the outbreak. Having a centralized repository for such information allows for earlier recognition of a widespread outbreak of a foodborne illness. Such syndromic surveillance is vital in today's environment where not only "natural" but terrorist threats to the food supply cannot be discounted. When more than a few cases of presumed foodborne

illness are identified, rapid identification of the type and source of the foodborne disease will limit the effects on a population.

CRITICAL INTERVENTIONS

- Rapidly provide adequate resuscitation to patients in hypovolemic shock from dehydration.
- Avoid early diagnostic closure; keep the possibility of more serious sequelae/disease processes in mind.
- Notify appropriate public health officials of potential foodborne illnesses, especially if multiple patients are identified.

DISPOSITION

Most patients can be safely discharged home after being rehydrated and demonstrating their ability to keep oral intake down. Discharge instructions should include maintaining a generous intake of fluid and beginning frequent small meals of solid food as soon as tolerated. Patients should be educated on signs and symptoms of dehydration, such as monitoring their urinary output. They should further be advised to return to the ED if symptoms recur, if they are unable to tolerate oral intake, or if they develop a fever or abdominal pain.

Patients with suspected bacteremia or who do not improve with standard therapy should be admitted to the hospital. Nonbacteremic patients may be suitable for observation status. Patients at the extremes of age, underlying comorbid conditions will usually need to be admitted. If the diagnosis is unclear and symptoms continue, admission will be necessary for further evaluation.

Common Pitfalls

- Failure to consider foodborne illness in all patients with nausea, vomiting, diarrhea, abdominal pain, and/or fever.
- Failure to obtain a history of antecedent antibiotic use, travel, camping or hiking, and diet specifics.
- Failure to consider other diagnoses such as appendicitis, aortic aneurysm, pyelonephritis, cholecystitis, pneumonia, pregnancy,

or myocardial infarction.
- Failure to consider the effects of comorbid diseases in the management of patient with foodborne illness.
- Discharging patients who cannot take oral fluids, especially if they have not been adequately resuscitated.
- Failure to notify public health authorities when treating a patient with suspected or confirmed foodborne illness.

SECTION XX
Hematologic/Oncologic Emergencies

Section Editor: JEFFREY J. SCHAIDER

CHAPTER 196 Bleeding Disorders

Emily Rose

Emergency physicians encounter bleeding on a daily basis. Lacerations, epistaxis, bruising, hematuria, gastrointestinal (GI) bleeding, and blunt and penetrating trauma are common complaints in the emergency department (ED). Most of these patients have normal clotting function and are bleeding because of a local lesion. This bleeding can be controlled by pressure, packing, suturing, or other local therapy aimed at the specific lesion, and bleeding does not recur if the lesion is properly treated.

In contrast, a patient with a bleeding disorder may bleed spontaneously as well as after trauma, and treatment of the local lesion often may not control the bleeding or prevent its recurrence. The disorder may be congenital or acquired and may involve one or more components of the body's complex coagulation system.

PATHOPHYSIOLOGY

Hemostasis is a complex and tightly regulated physiologic process that involves formation of a blood clot at a site of vessel injury while maintaining normal blood flow elsewhere in the body. There are three phases: (1) primary hemostasis, (2) secondary hemostasis, and (3) fibrinolysis (1).

Primary hemostasis involves the formation of a platelet plug and requires healthy blood vessels, von Willebrand factor (VWF), and a sufficient number of normal functioning platelets. Platelets do not adhere to surfaces or aggregate in healthy blood vessels with normal flow. Vessel injury exposes platelets to subendothelial matrix and triggers platelet adhesion to damaged endothelium or exposed

subendothelial components (2). VWF mediates initial platelet adhesion to sites of vascular injury, facilitates platelet aggregation, and acts as a carrier of FVIII (thus protecting it from cleavage and prolonging the factor's half-life in circulation). Following adhesion, agonists such as collagen and thrombin and some agents produced by the platelet itself trigger platelet activation. Platelets change from a disc shape to a spherical shape and increase contact with other platelets. Platelets are then triggered to secrete several substances that enhance further platelet plug formation, which continues through this positive feedback mechanism (3,4).

Secondary hemostasis involves the formation of fibrin strands by activation of the coagulation cascade. This fibrin mesh is incorporated into and around the initial platelet plug, strengthening and further stabilizing the clot (2).

The coagulation cascade has traditionally been separated into three pathways: the intrinsic, extrinsic, and the common pathways. The classical description of the extrinsic and intrinsic pathways has largely been disregarded as it does not correlate well with the in vivo process (3). It is presented in Figure 196.1 for demonstration of the action of anticoagulants and rationale of clotting studies. In the current understanding of coagulation, tissue factor (TF) is exposed, with endothelial injury which initiates coagulation (see Fig. 196.2). TF combines with activated factor VII (FVII), and this complex activates factor X (FX) and factor IX (FIX). Activated FX catalyzes the conversion of factor II (prothrombin) into thrombin (FIIa). In the amplification phase, thrombin activates platelets which results in assembly of coagulation factors on the platelet membrane and release of granule contents. Thrombin also activates factors V, VIII, and FXI. Factor XIII is activated by thrombin and is responsible for creating stable fibrin clot which prevents early removal of the clot by the fibrinolytic system. Endogenous anticoagulants such as antithrombin III, protein C, and protein S and TF pathway inhibitor act to degrade activated coagulation factors and thereby limit further coagulation (1).

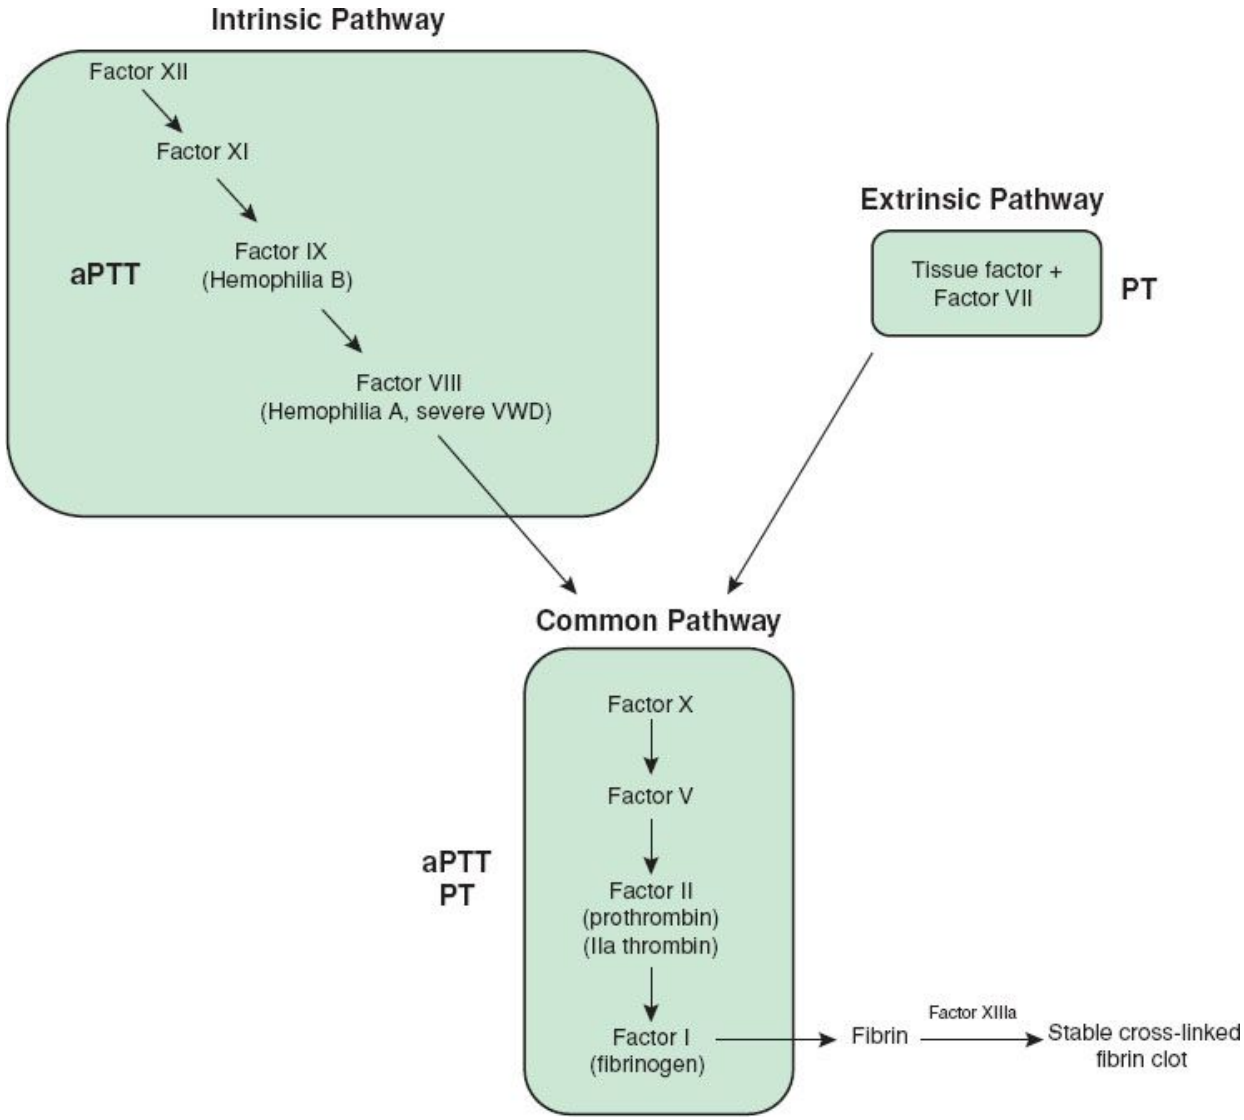

FIGURE 196.1 Simplified Coagulation Cascade. Factors VIII, IX, XI, and XII make up the intrinsic pathway. Deficiency of factors of the intrinsic pathway is measured by the activated partial thromboplastin time (aPTT). Extrinsic pathway factor VII is measured by the prothrombin time (PT). Both pathways join to form the common pathway which involves factors I, II, V, and X. Deficiencies in these factors may prolong both the aPTT and PT.

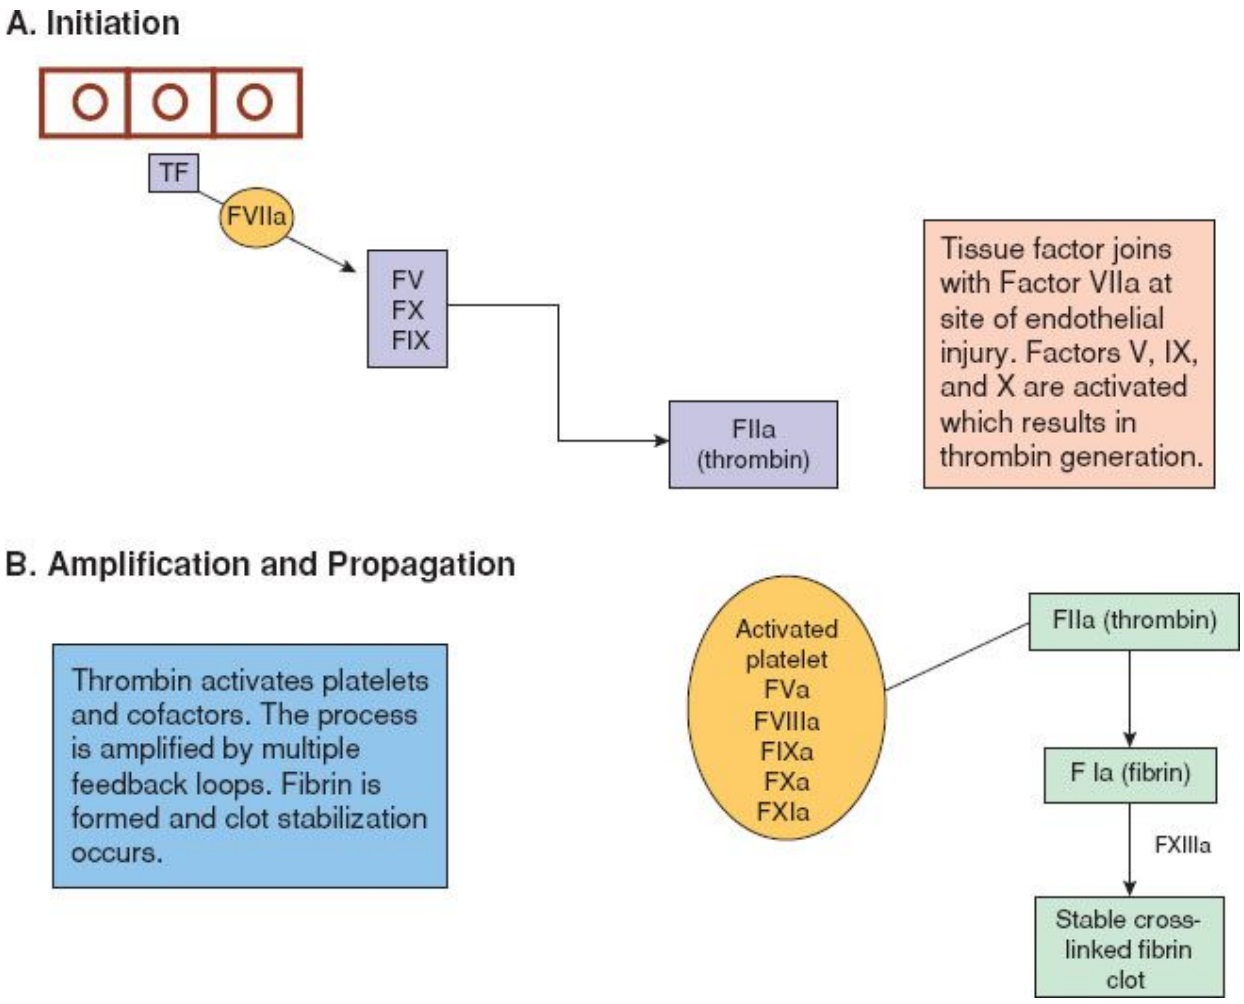

FIGURE 196.2 Simplified in vivo Coagulation Model. **A:** Initiation phase: Tissue factor (TF) joins with factor VIIa (FVIIa) at the site of endothelial injury. Factors V, IX, and X are subsequently activated and a small amount of thrombin is generated. **B:** Amplification and propagation: Thrombin then activates platelets and cofactors, many of which assemble on the surface of the platelet. Multiple feedback loops occur to amplify the process. Prothrombin is converted to thrombin which converts fibrinogen to fibrin and a stable cross-linked fibrin clot is formed.

Fibrinolysis is the process in which the fibrin clot is broken down into degradation products. The fibrinolytic system is activated by many of the same substances that activate the clotting cascade. Active plasmin cleaves fibrin to lyse the clot. Activation of

plasminogen by substances found in the clot localizes fibrinolysis to the clot (5).

When all systems operate in a normal, balanced fashion, there is neither unchecked hemorrhage nor thrombosis in the vascular tree. However, when an inherited or acquired disorder produces an abnormality in one or more components of the system, bleeding may occur. The abnormality may be in the structure of the vascular tree; in the number of platelets; in the platelets' functional ability; in the activity of clotting factors; or in the activity of the fibrinolytic system. The emergency physician must use information from the clinical and laboratory evaluation to identify the abnormal component and treat the patient properly.

CLINICAL PRESENTATION

Bleeding disorders may be congenital or acquired. Disorders may affect primary hemostasis, secondary hemostasis, or both.

Disorders of Primary Hemostasis

Disorders of primary hemostasis include the rare inherited disorders of platelet function, some types of von Willebrand disease (VWD), vascular anomalies (e.g., hereditary hemorrhagic telangiectasia, and Ehlers–Danlos) and acquired conditions such as immune thrombocytopenic purpura (ITP), systemic illness (e.g., renal and liver disease), and medication-induced effects (e.g., aspirin). Typical bleeding symptoms of these conditions include easy bruising, epistaxis, menorrhagia, mucocutaneous bleeding, and postoperative hemorrhage. Bleeding is typically immediate (in contrast to delayed bleeding that occurs in disorders of secondary hemostasis).

Von Willebrand Disease

VWD is the most common inherited bleeding disorder and may affect as much as 1% of the population. There are six different subtypes of VWD and the majority are inherited via autosomal dominant transmission. The clinical presentation and disease severity vary depending on the subtype. Mild-to-moderate mucocutaneous

bleeding predominates and patients present with bruising (often in absence of trauma), epistaxis, prolonged bleeding after dental extraction, menorrhagia, and prolonged/excessive bleeding after childbirth or operative intervention (4). More severe subtypes of VWD present similarly to hemophilia A because there is a functional deficiency of FVIII (6).

Platelet Disorders

Most platelet function disorders are acquired and may be secondary to medication or underlying disease. Inherited platelet function disorders such as Glanzmann thrombasthenia, Bernard–Soulier syndrome, and Wiskott–Aldrich syndrome are rare and present similarly to other disorders of primary hemostasis. Common medications that disrupt normal platelet function include nonsteroidal anti-inflammatory drugs (NSAIDs), aspirin, valproic acid, β-lactam antibiotics, and selective serotonin reuptake inhibitors (4). Systemic diseases such as renal failure, liver disease, and malignancy may also induce platelet dysfunction (7).

Immune Thrombocytopenic Purpura

The most common cause of thrombocytopenia secondary to platelet destruction is immune ITP. ITP is seen both in children and adults who were previously healthy. Increased platelet destruction occurs in the spleen along with inhibition of platelet production via autoantibodies. It is immune-mediated and may have no underlying cause (idiopathic/primary) or be associated with an underlying disorder (secondary) (8). Most children with ITP are 2 to 6 years old and many have had a recent viral illness. Otherwise, the history and physical examination are lacking symptoms and signs such as fever, weight loss, anorexia, bone pain, adenopathy, masses, or hepatosplenomegaly that would suggest a more serious condition such as leukemia. Typically, the only examination abnormalities are signs of platelet-type bleeding such as petechiae, bruises, subconjunctival hemorrhage, and signs of mucosal bleeding such as epistaxis. Adult ITP is most common in patients between the ages of

18 and 40 years. The examination in both groups should emphasize detection of life-threatening bleeding, for example, in the central nervous system (CNS), and of signs of other thrombocytopenic conditions such as disseminated intravascular coagulation (DIC), thrombotic thrombocytopenic purpura (TTP), or leukemia (8).

Disorders of Secondary Hemostasis

Disorders of secondary hemostasis (i.e., coagulation factor deficiencies) typically present with bleeding into soft tissues, muscles, and joints. Bleeding may not start until hours after trauma and may recur at a later time. Platelets function normally to form an initial plug but a stable, fibrin clot is not properly formed. Normal fibrinolysis then results in delayed bleeding (1).

Hemophilia

Hemophilia A and B are the most common inherited factor deficiencies. They are both sex-linked recessive disorders that result in deficiencies of clotting factor VIII (hemophilia A) and IX (hemophilia B). There are approximately 12,000 affected individuals in the United States with hemophilia A and about 30,000 with hemophilia B. Both factors VIII and IX play an important role in the formation of a fibrin clot. Disease severity typically correlates with the degree of factor deficiency. Patients with severe hemophilia have a clotting-factor level of $<1\%$, moderate hemophiliacs have a level between 1% and 5%, and mild hemophilia has a factor level between 6% and 40%. Rarely, a patient with hemophilia will have a concomitant procoagulant deficiency (e.g., Protein C/S or factor V Leiden) and have a less severe clinical presentation than measured factor levels would indicate (1,6,9).

The classic bleeding episode of the severe hemophiliac is spontaneous, painful hemarthrosis of joints (most commonly knees, elbows, and ankles). Patients with moderate hemophilia do not typically develop hemarthrosis but may experience severe muscular and soft tissue bleeding after trauma. Patients with mild disease may only have bleeding episodes associated with trauma and surgical

procedures (6). Recurrent joint bleeds lead to irreversible joint damage (hemophilia arthropathy). To maintain quality of life, severe hemophiliacs are on prophylactic clotting-factor treatment to prevent bleeding episodes.

Other factor deficiencies are rare. Most are also inherited in an autosomal recessive pattern.

Malabsorption may lead to impaired vitamin K absorption. Severe liver disease and/or DIC cause impaired production or concentration of almost all coagulation factors.

Disorders of Both Primary and Secondary Hemostases

Some bleeding disorders combine features of both platelet and clotting-factor deficiencies. Examples include DIC, liver disease, and severe VWD. VWD results from a deficiency in the complex of two proteins, factor VIII and VWF, that circulate together in plasma. Most patients with VWD have bleeding typical of a platelet disorder, but those with severe disease display both mucosal and deep bleeding.

Palpable hematomas, large bruises or ecchymosis in unusual places (such as thorax or back) may suggest both primary and secondary bleeding disorders (4).

Other Bleeding Disorders

Patients with acquired bleeding disorders are more likely to have an underlying illness that affects platelet number or function or clotting-factor levels (e.g., hepatic or renal disorder, disseminated intravascular coagulation [DIC], cancer, or an immunologic process) (see Table 196.1). The development of acquired inhibitors to individual clotting factors is rare in nonhemophiliac patients but is associated with severe, often fatal, bleeding. Factor VIII inhibitors are, by far, the most common. Patients are usually previously healthy individuals, who are often older, and who are often with a history of recent minor injury or surgery. Most do not have a history of major bleeding or a family history of inhibitors. Eighteen percent have an autoimmune disease; 5% note recent penicillin, sulfa, or other drug use. Some postpartum cases have been reported (10,11).

TABLE 196.1
Acquired Hemostatic Defects Associated with Selected Underlying Clinical Conditions

Underlying Clinical Condition	Type of Hemostatic Defect	Cause
Liver disease	Factor deficiency	Decreased synthesis
	Fibrinolysis	Decreased clearance of activators
	Hypercoagulable state	Antithrombin III and protein C deficiency, decreased clearance of activated clotting factors
	Thrombocytopenia	Splenic sequestration
Renal disease	Thrombocytopenia	Decreased marrow production
	Platelet defect	Retained metabolites in the blood
Malabsorption	Multiple factor deficiency	Vitamin K malabsorption
Acute leukemia (especially promyelocytic)	Thrombocytopenia	Decreased megakaryocytopoiesis
	Disseminated intravascular coagulopathy	Increased cellular procoagulant activity
Myeloproliferative disease	Platelet defect	Abnormal thrombopoiesis
	Thrombocythemia/thrombocytopenia	Hyperplastic or replaced (fibrotic) marrow, splenic sequestration
Lymphoma/chronic lymphocytic leukemia	Decreased von Willebrand factor	Adsorption onto tumor, autoantibody
	Low factor VIII	Autoantibody
	Thrombocytopenia	Marrow replacement, splenic sequestration
Dysproteinemia	Thrombocytopenia	Decreased marrow production
	Prolonged thrombin time	Inhibition of fibrin monomer polymerization
Amyloidosis	Factor X deficiency	Adsorption by amyloid
	Capillary fragility	Amyloid vascular infiltration
Systemic lupus	Lupus inhibitor[a]	Antibody to acidic phospholipids
	Factor deficiency	Autoantibodies to coagulation proteins
	Thrombocytopenia/thrombocytopathia	Autoantibodies to platelet glycoproteins

[a]Although the lupus inhibitor produces prolongation of clotting assay results and may exist coincidentally in patients with thrombocytopenia or clotting-factor deficiency that predisposes to bleeding, the lupus inhibitor itself is characterized by a thrombotic rather than a hemorrhagic tendency.

Adapted from White GC, Marder VJ, Colman RW, et al. Acquired disorders of hemostasis. In: Colman RW, Hirsh J, Marder VJ, et al., eds. *Hemostasis and Thrombosis, Basic Principles and Clinical Practice*. 3rd ed. Philadelphia, PA: JB Lippincott Co.; 1994.

Acquired bleeding disorders are often linked to the use of medications that interfere with normal coagulation (e.g., warfarin [Coumadin], heparin, aspirin, NSAIDs, glycoprotein IIb/IIIa inhibitors, direct factor Xa inhibitors, and direct thrombin inhibitors) (see Chapter 198). The effects of aspirin on platelet function are irreversible, lasting the 7- to 10-day lifespan of the platelet; those of NSAIDs last about three to five drug half-lives, after which platelets again participate normally in clot formation. More than 100 drugs are associated with the development of thrombocytopenia (see Table 196.2).

TABLE 196.2
Acquired Disorders of Hemostasis Associated with Drugs

Platelet Function Defects	Thrombocytopenia
Aspirin	Immune Destruction
Nonsteroidal anti-inflammatory drugs	Heparin
Heparin	Quinidine
Dipyridamole	Quinine
Theophylline	Gold
Penicillins	H_2 antagonists
Cephalosporins	Phenytoin
Tricyclic antidepressants	Antibiotics
Phenothiazines	Methyldopa
Clofibrate	Decreased Production
Antihistamines	Ethanol
Ethanol	Thiazides
Dextrans	Chemotherapeutic agents
Selective Serotonin Reuptake Inhibitors	**Coagulation Factor Deficiencies**
	Warfarin
	Penicillins
	Cephalosporins

Hemorrhagic disease of the newborn caused by inadequate vitamin K intake or absorption presents in the first days to weeks of life. Most cases can be prevented by prophylactic vitamin K administration in the newborn period.

The physical examination is directed toward identifying all bleeding sites and recognizing signs of underlying illness. Jaundice, organomegaly, adenopathy, and abnormal masses are sought.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of an acutely bleeding patient can be broken down into congenital (chronic history) versus acquired conditions (occurring over days to weeks) and disorders of primary hemostasis, secondary hemostasis, or both (discussed above). Family history may give important information such as sex-linked inheritance of hemophilia and autosomal dominant inheritance of VWD. However, 30% to 40% of hemophilia occurs from a new, spontaneous mutation and these cases will not have a positive family history (12). Severe congenital coagulation disorders typically

present early in life whereas mild disorders may not present until well into adulthood. It is imperative, particularly in a non-mobile child with bruising, that the emergency physician *always* consider the possibility of non-accidental trauma.

ED EVALUATION

ED evaluation of coagulopathy includes the activated partial thromboplastin time (aPTT), the prothrombin time (PT), and a complete blood count (CBC) with platelet count. The aPTT detects abnormalities of the intrinsic and common pathways and is prolonged by deficiencies of high–molecular-weight kininogen; prekallikrein; factors XII, XI, IX, VIII, X, V, and II; and fibrinogen. The aPTT is also prolonged in the presence of antiphospholipid antibody (formerly termed the *lupus anticoagulant*) and by heparin, warfarin, and fibrin-degradation products. The PT reflects the activity of the factors of the extrinsic and common pathways. It is prolonged by deficiencies of factors VII, X, V, and II and fibrinogen; by warfarin; and by heparin in high concentrations. The PT is more affected by reduced levels of factors VII, V, and X than by decreases in factor II and fibrinogen (see Fig. 196.3) (13).

Normal PT Normal aPTT	↑ PT Normal aPTT
CONGENITAL: FXIII, α_2-antiplasmin, plasminogen activator inhibitor I deficiency **ACQUIRED:** Vitamin C deficiency	**CONGENITAL:** FVII deficiency **ACQUIRED:** Mild vitamin K deficiency, vitamin K antagonists
Normal PT **↑ aPTT**	**↑ PT** **↑ aPTT**
CONGENITAL: FVIII, FIX, FXI, FXIII, PK, HMWK deficiency, VWD **ACQUIRED:** Heparin, factor inhibitors, lupus anticoagulans	**CONGENITAL:** FX, FV, FII deficiency, fibrinogen disorder, combined FV/FVIII deficiency **ACQUIRED:** Severe vitamin K deficiency, liver disease, excess vitamin K antagonist, heparin, DIC

FIGURE 196.3 Effect of various inherited and acquired bleeding disorders on the laboratory tests PT and aPTT. (Modified from Van Herrewegen F, Meijers JCM, Peters M, et al. The bleeding child. Part II: Disorders of secondary hemostasis and fibrinolysis. *Eur J Pediatr*. 2012;171:207–214.)

Patients with factor VIII and IX deficiencies (hemophilia A, B, and some forms of VWD) have a prolonged aPTT and a normal PT. Patients with a normal aPTT and a prolonged PT have a factor VII deficiency, because that is the only factor of the extrinsic pathway not involved in the common pathway. Isolated factor VII deficiency occurs as a rare congenital abnormality and is seen in the acquired form in mild liver disease and in the initial stages of oral anticoagulation or vitamin K deficiency. Although the aPTT, as well as the PT, are prolonged in the fully warfarinized patient, the PT is used for monitoring because of its simplicity. Both the PT and the aPTT are prolonged in moderate-to-severe liver disease, vitamin K deficiency, heparin and warfarin use, afibrinogenemia, and consumptive coagulopathies such as DIC (5).

Specific factor assays can be done to confirm the diagnosis suspected from the history or from abnormalities of the screening PT and aPTT and to provide exact activity levels. However, these assays are rarely available on an emergency basis, and emergency treatment must be initiated without the benefit of such tests.

The CBC is used to assess the degree of anemia produced by the bleeding. The CBC also reveals abnormalities of the white blood cell count, which might suggest leukemia as the etiology of the more clinically obvious thrombocytopenia. Examination of the peripheral blood smear will detect platelet clumping that causes a falsely low platelet count as well as abnormalities of red- and white blood cell number and morphology.

The platelet count is the first step in the evaluation of possible platelet disorders such as ITP or TTP. Patients with counts $<100{,}000/\mu L$ are considered thrombocytopenic; if platelet function is normal, the bleeding time increases in direct proportion to the decrease of the count below 100,000/μL. Platelet counts $>50{,}000$ to

60,000/μL are usually sufficient to control bleeding caused by trauma or local pathology. Patients with platelet counts <5,000 to 10,000/μL are at risk for spontaneous bleeding. However, the platelet count should never be the only criterion considered when assessing a patient's risk of hemorrhage. The underlying condition leading to thrombocytopenia must be sought, and platelet function must also be considered.

No tests are available on an emergency basis that specifically screen for platelet function, as opposed to platelet number. A thorough history and physical examination may suggest that the patient is at risk for a functional platelet disorder (e.g., alcohol or aspirin use). Platelet function has traditionally been measured by the bleeding time. However, bleeding time is invasive, not sensitive or specific, time-consuming, difficult to perform and no has standardized normal for children. It has largely been replaced by the PFA-100 (platelet function analyzer). The PFA-100 is sensitive for platelet defects and severe VWD but may not pick up mild disorders (van Ommen). A few bleeding disorders produce no abnormalities in the available screening tests. Patients with vascular disorders, simple and senile purpura, factor XIII deficiency, and mild forms of other factor deficiencies (factor levels >20% to 25% of normal) have normal aPTTs, PTs, and platelet counts (5).

Whole blood viscoelastic assays such as thrombelastography and rotational thromboelastometry have been shown to be superior in prediction the need for and directing blood transfusion in patients with severe bleeding in nonhemophiliac patients (14–17). These assays may be useful to monitor hemostasis in inhibitor-expressing patients with hemophilia (16).

ED MANAGEMENT

Initial management of the bleeding patient includes airway control, if necessary, adequate ventilation, and oxygenation. If bleeding has led to hypovolemia, crystalloid resuscitation and packed red blood cells should be administered. Local measures should be used to control bleeding (e.g., pressure, packing, suturing, immobilization). See Table 196.3 for treatment options in acute bleeding episodes.

TABLE 196.3
Treatment Options in Acute Bleeding Episodes

Medication	Dose	Indication	Notes
Fresh-frozen plasma (FFP)	10–15 mL/kg IV	Hemophilia B, coagulopathy secondary to factor deficiencies	Use only when FIX concentrates are not available
Cryoprecipitate	1 bag per 6–10 kg every 8–12 hrs	Hemophilia A, VWD, uremia	Use only when FVIII concentrates not available
Platelets	Adults: 1 RDP Children: 5–10 mL/kg	Acute bleeding secondary to platelet deficiency	Restricted to severe, life-threatening bleeding in TTP-HUS, HIT, and DIC
Aminocaproic acid (Amicar)	50–100 mg/kg orally or IV, then 50 mg/kg every 6 hrs	Mucosal bleeding	Prevents dissolution of a hemostatic plug. Avoid in hemophiliacs with hematuria
Factor VIII	20–100 IU/kg every 12–24 hrs	Hemophilia A	See Table 196.5 for % correction recommendations
Factor IX	20–100 IU/kg every 24 hrs	Hemophilia B	See Table 196.5 for % correction recommendations
Factor VIIa	90–120 µg/kg, repeat every 2 hrs	Hemophilia with inhibitors	Off label use for other acute bleeding episodes
VWF Concentrate	20–30 IU/kg (mild bleeding) 50–60 IU/kg (severe bleeding)	VWD, hemophilia A	See Table 196.5
DDAVP	See Table 196.4 for IN, IV, SQ dosing	VWD, hemophilia A, uremia, platelet dysfunction	See Table 196.4
APCC	50–100 IU/kg/dose IV (max 200 IU/kg/d)	Hemophilia with inhibitors	Laboratory tests do not correlate with clinical efficacy
Fibrin sealants, topical thrombin, microfibrillar collagen	Apply to bleeding surface	Local bleeding	Many commercially available; foam, granules, bandages; fibrin sealants often applied with two syringes or Y-connector and tubing

Modified from Rose EAC. Inherited bleeding disorders in infants. In: Sharieff GQ, McCollough M, eds. *Neonatal and Infant Emergencies*. 1st ed. Philadelphia, PA: Cambridge Press; 2009:242–254.

Platelet Disorders and Disorders of Primary Hemostasis

Platelet transfusion should be initiated if there is active bleeding unresponsive to local measures and typical of that caused by a platelet disorder (see Table 196.3) and the platelet count is <50,000/µL. Active bleeding with a platelet count >50,000/µL should prompt a search for another cause of bleeding, such as a functional platelet disorder, a coagulation factor deficiency, or an untreated primary bleeding site (18).

Platelets play an essential role in the maintenance of vascular endothelial integrity and that a minimum number are required to fulfill that function. Below this threshold, thinning and fenestration of the endothelium may lead to spontaneous bleeding. Studies suggest that 5,000 to 10,000 platelets/µL can maintain vascular integrity and that prophylactic transfusion should be given for values below that to prevent intracranial hemorrhage and other significant bleeding. Mucosal bleeding and epistaxis are more predictive of serious bleeding than merely the presence of petechiae and ecchymosis (4). A platelet count of 40,000 to 50,000/µL is sufficient for most procedures including lumbar puncture in the absence of functional platelet defects. A platelet count of 20,000/µL is sufficient

for central venous catheter placement and lumbar puncture in patients with hematologic malignancies (18).

The standard dose of platelets is one random donor platelet (RDP) unit per kg of body weight (4 to 6 units of pooled platelets or one apheresis unit). One RDP unit raises the platelet count by 7,000 to 10,000/μL in healthy adults. Pediatric dosing is 5 to 10 mL/kg. A smaller rise in platelet count may occur in ill, bleeding patients and those with platelet destructive or platelet consumptive disorders and these patients may require repeat transfusion (18). Patients with life-threatening bleeding should be transfused regardless of the etiology of thrombocytopenia. Thrombotic thrombocytopenic purpura-hemolytic uremic syndrome (TTP-HUS), heparin-induced thrombocytopenia (HIT), and DIC are all associated with platelet consumption and they can cause thrombosis as well as bleeding. Because of the thrombotic risk, platelet transfusion is generally considered to be relatively contraindicated in these conditions, and guidance should be sought through hematology consultation (18).

Immune Thrombocytopenic Purpura

Life-threatening bleeding in ITP is treated initially with platelet transfusion, high-dose intravenous steroids and IVIG (1 g/kg/d) for 2 to 3 days (19). The treatment of ITP without acute bleeding depends on the age of the patient. Many children do not receive treatment because 70% to 80% have complete disease remission within 6 months (19). Treatment of ITP in children has not been proven to decrease incidence of intracranial hemorrhage, the most feared complication of ITP (19). Spontaneous remission of ITP occurs in $<$10% adults and so most adults are treated when the platelet count is $<$30,000/μL. First-line therapy includes oral or intravenous glucocorticoids which support the platelet count until spontaneous remission can occur. Prednisone (1 to 2 mg/kg for children and 1 mg/kg for adults per day) is most commonly used. Duration of treatment depends on platelet response. High-dose methylprednisolone (30 mg/kg initially) is used in children and adults resistant to oral prednisone. Length of steroid therapy is determined by platelet response. Other first-line therapies include

IVIG (1 g/kg/d for 1 to 2 days) or IV anti-D globulin (50 to 75 μg/kg/d, given once). Anti-D globulin is only effective in Rh-positive patients with an intact spleen. Both IVIG and anti-Rh(D) increase platelet counts in most patients within several days and the effect may last several weeks. They may cause mild alloimmune hemolysis and intravascular hemolysis may rarely occur with anti-D therapy. It should not be given in patients with an Hbg <8 g/dL. Splenectomy is an effective treatment in persistent cases of ITP and considered as a second-line therapy. Agents such as rituximab and immunosuppressants may be used in resistant cases. Bone marrow evaluation is recommended if there are abnormalities of other cell lines in addition to platelets or with systemic symptoms such as bone pain or splenomegaly (4,8,19). Hemostatic defects in uremia are multifactorial but are primarily related to defects in platelet function. Significant coagulation factor deficiencies occur only in the severely nephrotic patient. Platelet counts are decreased but rarely $<100{,}000/\mu L$. The functional platelet defect is due to toxic retained metabolites, which can quickly reduce the effectiveness of newly transfused platelets. Dialysis at least partially reverses this toxic effect but may not be immediately available for the bleeding patient. Desmopressin (1-deamino-8-D-arginine vasopressin [DDAVP]) and conjugated estrogens may be used along with platelets in management of the acutely bleeding uremic patient (see Table 196.4 for DDAVP dosage and administration). Maintaining a hemoglobin ≤ 10 g/dL also appears to decrease bleeding time in uremia (20).

TABLE 196.4
Desmopressin (DDAVP) Dose and Administration

Intranasal	<50 kg: 150 μg IN (one spray into one nostril)
	≥50 kg: 300 μg IN (one spray into each nostril)
Intravenous	0.3 μg/kg diluted into normal saline (15–30 mL for children and 50–100 mL for adults). Administered over 15–30 min
Subcutaneous	0.3 μg/kg

Von Willebrand Disease

Bleeding patients with VWD need increased plasma levels of VWF and FVIII. In patients with mild VWD, DDAVP is the treatment of choice. DDAVP stimulates the release of VWF and effectively raises plasma concentration of both VWF and FVIII. It may be administered through intravenous, subcutaneous, and intranasal routes (see Table 196.4). Side effects include mild tachycardia, flushing, and headache. DDAVP is a potent antidiuretic agent and hyponatremia potentially resulting in a seizure may occur if the sodium decreases significantly. Water restriction and avoidance of hypotonic intravenous fluids are recommended. DDAVP will not work in patients with nephrogenic diabetes insipidus. Rarely, arterial thrombotic events may occur such as stroke and myocardial infarction. DDAVP will not be effective in type 3 VWD and severe hemophilia A (4,6,7).

More severe forms of VWD require FVIII/VWF concentrates (see Table 196.5). High-purity FVIII concentrates contain no VWF. Minor bleeds require 30 to 50 IU/kg of FVIII/VWF product and major bleeds 40 to 60 IU/kg (6). Antifibrinolytic therapies such as epsilon-aminocaproic acid or tranexamic acid are helpful adjuncts for bleeding. Topical adjunctive hemostatic preparations may be applied to exposed sites of bleeding as well.

TABLE 196.5
Factor Replacement Guidelines in Hemophilia A, Hemophilia B, and von Willebrand Disease

Bleeding Type	%Correction	Hemophilia A (Factor VIII)	Hemophilia B (Factor IX)	VWD (VWF:RCo)
MINOR (e.g., hemarthrosis, hematoma, minor laceration, fracture)	40–50	20–50 IU/kg every 12–24 hrs for 1–3 doses	20–60 IU/kg every 24 hrs for 1–3 doses	Local measures, DDAVP. Rarely, VWF:RCo 15–25 IU/kg is required
MAJOR (ICH, preoperative, significant trauma severe joint/muscle bleed, compartment syndrome)	80–100	50–100 IU/kg every 8–12 hrs; Continuous infusion of 2–5 IU/kg/hrs may be given after initial bolus in severe cases	50–100 IU/kg every 12–24 hrs; Continuous infusion of 5–10 IU/kg/hrs after initial bolus in severe cases	40–80 IU/kg Load and 40–60 IU/kg every 8–12 hrs

IU, International units, RCo, Ristocetin cofactor.

Emergency Department care for patients with hemophilia and von Willebrand Disease. *J Emerg Med*. 2010;39(2):158–165.

Coagulation Disorders and Disorders of Secondary Hemostasis

If the clinical evaluation suggests a congenital single-factor deficiency (e.g., hemophilia A or B), the location of the bleeding determines the therapeutic approach (see Table 196.5). Bleeding into the CNS, neck, sublingual, retroperitoneal spaces, and GI tract is immediately life-threatening. All hemophiliacs with suspected bleeding in these high-risk sites should receive immediate factor replacement therapy to achieve a factor level of 100% of normal. One U of factor VIII per kg of body weight will raise the patient's level by 2%, so 50 U/kg should be given. The ideal body weight rather than actual body weight should be used (21). One U of factor IX per kg raises the level by only 1%, so patients with hemophilia B require 100 U/kg in life-threatening situations (see Table 196.5) (6). This therapy should be initiated without waiting for the results of the aPTT, factor levels, head CT, or other scans. The half-life of factor VIII is 8 to 12 hours, so maintenance therapy should be infused two to three times per day or given as a continuous infusion. Factor IX maintenance therapy is given every 18 to 24 hours. Factor administration should be continued for 14 days if bleeding is located in the CNS, neck, or retroperitoneum (6). A low threshold for admission for observation should be maintained for patients with injury or suspected bleeding in the high-risk sites.

Patients with bleeding disorders are at a higher risk for life-threatening intracranial hemorrhage that may occur spontaneously or after minor head injury. In a large, prospective multicenter study of children with minor blunt head trauma, children with bleeding disorders were twice as likely to be imaged as those without. However, only approximately 1% of patients with both acquired and congenital bleeding disorders sustained an intracranial hemorrhage (22). Vigilance should be maintained about the possibility of intracranial hemorrhage with a low threshold to obtain imaging. However, the risk versus benefit of irradiation from a CT scan must always be assessed, particularly in a young patient at risk for cumulative radiation exposures.

Minor bleeding into the soft tissues, muscles, oral cavity, urinary tract, and limited hemarthrosis can be treated with 20 to 40 U/kg (1,6). Patients with massive hemarthrosis and bleeding into large joints such as the hip and shoulder should receive at least three doses of 50 U/kg. The presence of limb hematomas should prompt a thorough search for signs of compartment syndrome. If this condition is suspected, 50 U/kg of the appropriate factor should be administered and surgical consultation should be obtained. However, most patients are observed 6 to 8 hours after the infusion for spontaneous resolution (10). Rest, ice, and compression, as well as crutches and limited weight bearing, should be prescribed after joint and limb bleeds, followed by physical therapy. The addition of antifibrinolytic therapy (tranexamic acid mouthwash and oral epsilon-aminocaproic acid) to combat the effects of saliva in cases of bleeding from oral mucosa, gums, anterior tongue, and dental extraction sites may hasten effective coagulation when used with factor infusion.

The safety of plasma-derived factors has improved with better screening of blood products and viral irradiation techniques. No HIV, hepatitis B, or hepatitis C seroconversion has been reported in previously unexposed hemophiliacs since 1987. However, recombinant factors VIII and IX are most commonly used in young hemophiliacs secondary to fear of transmission of new and/or unknown pathogens. The choice of the appropriate factor VIII product for each hemophilic patient is one that should be made in concert with the patient's hematologist, if possible. All currently marketed factor VIII products are considered safe from the standpoint of HIV, hepatitis B, and hepatitis C transmission. High-purity products are those from which nonfactor VIII protein contaminants have been removed. These products should be used in HIV-positive hemophiliacs to protect against the development of anergy and lowering of CD4 counts that can occur with less pure products. Intermediate-purity products contain plasma protein, but not viral contaminants. Recombinant factor products cost two to three times more than plasma-derived products and are sometimes in short supply because of limited manufacturing capacity.

Recombinant factor products are prescribed most often for newly diagnosed hemophiliacs and for those in whom no blood-borne infections have developed.

Because recurrent joint bleeds are so debilitating, many severe hemophiliacs are on prophylactic treatment with factor concentrates. Prophylactic treatments have successfully prevented significant bleeding in severe hemophiliacs and allowed many with severe hemophilia to lead a near-normal lifestyle (23).

Noncritical bleeding in patients with mild hemophilia A (with baseline FVIII levels >10%) may be responsive to DDAVP (see Table 196.4 for DDAVP dosage and administration). A three- to fivefold increase in factor VIII and VWF may occur with peak effects 30 to 60 minutes after the dose (7).

Treatment advances have allowed hemophiliacs to have a longer life expectancy than ever before. This has brought new management challenges as older hemophiliacs are developing conditions such as cardiovascular disease and cancer. Treatment of hemophiliacs with these complex conditions are currently managed by expert consensus and evidence-based management has not yet been formulated (23,24). An example of recommendation for surgery is normalizing the coagulopathic condition with continuous factor infusion and then treating the patient as if they were not coagulopathic with prophylactic doses of low–molecular-weight heparin (24).

The future may hold the definitive cure of hemophilia with gene transfer therapy. Another goal in hemophilia management is wider treatment availability to the third world.

The most challenging aspect of hemophilia management is the development of inhibitory alloantibodies against FVIII or FIX. Inhibitors render treatment with factor replacement concentrates ineffective in achieving hemostasis. They occur in approximately 20% to 30% of severe hemophilia A and 3% to 5% of those with hemophilia B (6,23). The mechanism of inhibitor production is not completely understood. Those treated with recombinant FVIII have a higher incidence of inhibitors than those treated with plasma-derived products. Inhibitors to VWF are extremely rare (6).

Patients with inhibitors are complex and their management should be directed in consultation with a hematologist. Inhibitors may be “low-responding” and can be overcome with large doses of factor concentrate. Patients with “high-responding” inhibitors require alternative factor agents. Two available agents for these patients include activated prothrombin complex concentrates, FEIBA-VH (Baxter Healthcare, Deerfield, IL) which contains activated vitamin K-dependent factors (II, VII, IX, X) and NovoSeven (Novo Nordisk Inc., Princeton, NJ), a recombinant activated factor VII. The superiority of one treatment has yet to be clearly established and both are accepted treatments for patients with inhibitors. The theorized underlying mechanism of action is enhanced thrombin generation on activated platelets leads to a more stable fibrin clot and hemostatic plug. Significant trauma or surgical intervention requires a minimum initial FVIIa dose of 120 μg/kg followed by repeat dosing every 2 hours.

The only proven therapy for inhibitors is controversial due to significant cost. Patient with inhibitors may undergo antigen-specific immune tolerance induction to eradicate inhibitors through long-term daily treatment of large doses of coagulation factors (23,25).

Inhibitors also occur de novo in nonhemophiliac patients, those directed against factor VIII being the most common. Treatment of life-threatening bleeding is similar to that described previously, which uses high doses of factor VIII concentrates, aPCCs, and recombinant factor VIIa. To arrest synthesis of the inhibitor, steroids and immunosuppressants, such as azathioprine or cyclophosphamide, are given (10,11).

Patients with complex conditions such as liver disease or DIC usually have deficiencies of multiple coagulation factors and, often, of platelets as well. If laboratory tests confirm these abnormalities and the patient is actively bleeding, fresh-frozen plasma and platelets are given to replace the needed components.

Because so many bleeding disorders are associated with underlying diseases, attention should always be directed to the potential associated condition while immediate lifesaving transfusions of blood components are provided.

CRITICAL INTERVENTIONS

- Initiate platelet transfusion if there is active bleeding that is unresponsive to local measures and the platelet count is $<50{,}000/\mu L$.
- Replace clotting factor to achieve a factor level of 100% of normal for hemophiliacs with suspected bleeding in high-risk sites. Give 50 U/kg of factor VIII or 100 U/kg of factor IX, depending on which factor deficiency exists. Initiate therapy before confirmatory testing.

DISPOSITION

Life-threatening bleeding in a patient with a bleeding disorder requires admission, often to a monitored setting. An acutely bleeding patient should be transferred to another facility only if a service unavailable at the initial hospital can be provided at the second facility. A patient with minor bleeding may be managed as an outpatient if the patient is reliable with good resources and if management can be closely coordinated with the patient's hematologist.

Common Pitfalls

- Failure to initiate treatment early (before imaging) in bleeding disorders.
- Failure to begin treatment with mild symptoms in severe hemophilia.
- Failure to recognize inhibitors and adjust management appropriately
- Failure to recognize how underlying coagulation disorders complicate the management of common injuries.
- Failure to involve pharmacy and hematology in complicated replacements or surgical procedures.

CHAPTER 197

Disseminated Intravascular Coagulation, Thrombotic Thrombocytopenic Purpura, and Hemolytic–Uremic Syndrome

David Beran

Several disease processes lead to thrombus formation in the microvascular circulation with resultant consumption of clotting components and, ultimately, organ dysfunction. The underlying pathologies of these conditions differ, but the clinical presentation of multisystem involvement with hemorrhage and thrombosis may be very similar. Careful history, physical examination, and laboratory analysis enable the emergency physician (EP) to differentiate these conditions and begin appropriate treatment and referral.

The unique pathophysiology, laboratory findings, and treatments of each condition are discussed in the following sections.

DISSEMINATED INTRAVASCULAR COAGULATION

Disseminated intravascular coagulation (DIC) is a condition where the clot-forming and clot-dissolving pathways are activated leading

to a state of simultaneous thrombus formation and hemorrhage. DIC does not occur alone, but secondary to other diseases which share the feature of causing the release of procoagulant substances. In the emergency department, commonly seen examples of such diseases include trauma (such as head injuries, burns, and crush injuries), sepsis, malignancy, obstetric conditions such as abruptio placenta or amniotic fluid embolism, and intravascular hemolysis, as with transfusion reactions (1,2).

The clot-forming coagulation cascade is activated through the release of tissue factor, leading to the formation of thrombin. Tissue factor is released in response to bacterial endotoxin, by tumor cells and secondary to severe trauma, intravascular hemolysis, and obstetric conditions (3–5).

Once generated, thrombin plays its normal pivotal role in coagulation, cleaving fibrinogen to form fibrin, activating the intrinsic pathway and platelets. Thrombin is also involved in the body's normal method of terminating the clotting process. As procoagulants are continuously released into the circulation, they drive the coagulation cascade and the coactive inhibitory mechanisms, yielding both fibrin clots throughout the vascular system and large amounts of inactivated factors. Further, inhibitors of the coagulation cascade such as antithrombin III (AT III) and tissue factor inhibitor are reduced via consumption and decreased synthesis leading to an even greater increase in coagulation and fibrin mesh formation. The fibrin mesh caused by the activated coagulation cascade traps circulating platelets, leading to concomitant hemorrhage.

Simultaneous with the coagulation cascade is the activation, then suppression, of the fibrinolytic system. Plasminogen activator release from endothelial cells activates plasmin which attacks fibrinogen-producing fibrin degradation products (FDPs) such as D-dimer. FDPs are significant as they interfere with the polymerization of fibrin, which is necessary to create functional clots. This further contributes to the hemorrhagic features of DIC.

This profibrinolytic response leads to a sustained increase in plasminogen-activator inhibitor type 1 (PAI-1), the major regulating enzyme of the fibrinolytic system. High levels of plasma PAI-1 has been shown as a strong predictor of mortality in select patient populations with DIC (6). Consequently, fibrinolysis cannot keep pace with intravascular coagulation and the microvasculature fills with occlusive thrombi—simply, the patient forms clots faster than they bleed but both are ongoing.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

DIC occurs in an acute, fulminant form and in a low-grade, chronic form. The acute form usually is associated with sepsis, trauma, and acute obstetric events where the chronic form is associated with underlying malignancy. The incidence of DIC in severe sepsis is 18% and in septic shock, 38% (5) with a prevalence of up to 50% in gram negative sepsis (7). Excessive bleeding in these clinical settings should cause suspicion of DIC. Petechiae, purpura, hemorrhagic bullae, and subcutaneous hematomas can be seen along with gastrointestinal, urinary tract, and pulmonary bleeding. Although hemorrhage may be impressive, it is organ failure that is the usual cause of death in DIC. This is caused at least partially by microvascular fibrin deposition in end organs (1,8).

The differential diagnosis for DIC includes other microangiopathic hemolytic anemias such as thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndrome (HUS) as well as primary hemostatic disorders and liver disease.

ED EVALUATION

The EP's initial role in evaluating the patient with DIC involves identifying disease processes associated with DIC. An appropriate clinical setting with a typical physical examination suggestive of DIC should spur the physician to seek laboratory evidence of the secondary diagnosis.

Readily available laboratory tests that confirm depletion of coagulation factors include the prothrombin time (PT), PTT, and fibrinogen level (1,8). The PT and PTT are prolonged in only about 50% of cases of DIC, because activated factors and degradation products may interfere with these tests. Therefore, PT and PTT testing cannot confirm or exclude the diagnosis. The fibrinogen level is less than 150 mg/dL in only 70% of cases, probably because it is an acute-phase reactant and is elevated in acute illness. Examination of the peripheral blood smear will show schistocytes in 50% of patients with fulminant DIC, as well as large platelet forms (1). Platelet counts range from 20,000 to 100,000/μL, averaging about 60,000/μL.

The consumption of coagulation inhibitors can be measured directly by checking the AT III level, which is decreased in 89% of patients with DIC; but this information is rarely available to the EP.

Activation of the fibrinolytic system can be assessed by measurement of FDPs and D-dimer levels. In one study, using a D-dimer assay for the diagnosis of DIC gave a sensitivity of 98%, specificity 86%, negative predictive value 99%, and positive predictive value 66%. The value of D-dimer in the evaluation of DIC thus rests in its high negative predictive value (9).

Because there is no single laboratory test that is diagnostic for DIC, scoring systems have been developed that assign points for clinical criteria and abnormal values for platelet count, PT, FDPs, and fibrinogen.

The system proposed by the International Society of Thrombosis and Haemostasis (ISTH) is designed to identify overt DIC. It has a sensitivity of 91% to 93% and a specificity of 97% to 98% (10). It must be applied to patients with an underlying disorder known to be associated with DIC and is calculated as follows:

Platelet count: $>100{,}000 \rightarrow 0$; $<100{,}000 \rightarrow 1$; $<50{,}000 \rightarrow 2$

FDP, D-dimer: no increase $\rightarrow$ 0; moderate increase $\rightarrow$ 2; strong increase $\rightarrow$ 3

Prolongation of PT: by <3 sec $\rightarrow$ 0; by >3 but <6 sec$\rightarrow$ 1; by >6 sec $\rightarrow$ 2

Fibrinogen level: >1.0 g/L $\rightarrow$ 0; <1.0 g/L $\rightarrow$ 1

$\rightarrow$

Scores ≤ 5 are compatible with overt DIC and are associated with a 28-day mortality rate of 40% to 70%. Those <5 are suggestive of nonovert DIC and portend a 25% to 35% mortality. The score should be repeated daily.

A scoring system for nonovert DIC has been developed by the Japanese Association for Acute Medicine. This system has been shown to detect DIC earlier in the disease process than the ISTH score and may therefore allow for earlier intervention (11). In this system, the clinician must first exclude confounding conditions prior to applying the score.

Once these are excluded the score is calculated as follows.

Number of Systemic Inflammatory Response Syndrome criteria:

3 or greater $\rightarrow$ 1; 2 or less $\rightarrow$ 0

Platelet count ($\times 10^9$/L):

<80 or $>50\%$ decrease in 24 hours $\rightarrow$ 3; >80 but <120 or $>30\%$ decrease in 24 hours $\rightarrow$ 2; >120 $\rightarrow$ 0

PT (value of patient/normal value):

>1.2 $\rightarrow$ 1; <1.2 $\rightarrow$ 0

Fibrin/FDPs (mg/L):

>25 $\rightarrow$ 3; >10 but <25 $\rightarrow$ 1; <10 $\rightarrow$ 0

A score ≤ 4 indicates a diagnosis of DIC.

Laboratory test results such as increased serum LDH or creatinine may reflect end-organ damage and be supportive of the diagnosis. Other useful tests are hemoglobin and hematocrit, urinalysis, pregnancy test, and imaging studies as guided by history and examination to search for the inciting illness.

KEY TESTING

- Complete blood count

- Comprehensive metabolic panel
- D-dimer
- International normalized ratio, PT/PTT
- Fibrinogen
- Serum pregnancy test
- Lactate dehydrogenase
- Peripheral blood smear
- Imaging as dictated by the presumed underlying disease process (eg. chest x-ray for presumed pneumonia, computed tomography (CT) for head trauma, etc.)
- If available, Antithrombin III level
- Cultures of blood and urine, as appropriate

ED MANAGEMENT

There is one area of universal agreement in DIC treatment: The underlying illness must be aggressively attacked. Early surgery, antibiotics, chemotherapy, or other appropriate therapy to stop the continuous activation of the coagulation cascade must be carried out (1,3,4,8). The EP's responsibility rests in the management of the underlying disease state and identification of illnesses associated with DIC. The EP should obtain laboratory data for their own guidance but recall that they may have the ability to order tests such as AT III or fibrinogen levels earlier, which may be useful to their consultants.

Indications for transfusion of blood products are similar in DIC and non-DIC patients. Transfusion of packed red blood cells, platelets, and fresh frozen plasma (FFP) follow standard indications. Although some clinicians fear "fueling the fire" of coagulation by giving FFP or cryoprecipitate to patients with DIC, this event has not been shown to occur in most cases (3,8). FFP should be given in patients with an international normalized ratio greater than 2, a twofold increase in aPTT or fibrinogen level less than 100 mg/dL, but will rarely be sufficient by itself to replete fibrinogen (12).

Heparin can partly inhibit the activation of coagulation in patients with DIC but has never been shown to have a significant

beneficial effect on survival in controlled trials. Its use in DIC is recommended in patients with obvious thromboembolic disease such as purpura fulminans and acral ischemia.

AT III has largely been studied in patients on the sepsis spectrum. Various studies have shown a decreased duration of symptoms, improved coagulation parameters, improved oxygenation, or a decrease in intensive care unit (ICU) and ventilator days, but none have demonstrated an actual mortality benefit.

CRITICAL INTERVENTIONS

- Early recognition and aggressive management of conditions associated with DIC
- Transfusion of blood products according to usual indications
- Early involvement of hematology and subspecialists needed to manage underlying disease state

DISPOSITION

The primary role of the EP is to stabilize these patients and obtain the necessary laboratory and imaging studies to screen for and identify the presence of DIC. The importance of immediate specialty consultation once DIC is suspected cannot be overemphasized, owing to the importance of treating the underlying cause. Further, antibiotics and replacement of blood component therapy should be initiated in the emergency department to best prepare the patient for the next phase of their care, be it surgical, medical, or oncologic. The prognosis in patients with DIC is poor and they will require intensive care. They should not be transferred from an institution that has facilities to care for them and their underlying disease process.

Common Pitfalls

- Failing to consider DIC as a complication of the conditions it is most frequently associated with. DIC should be sought in all patients at risk.

- Allowing bleeding to distract the physician from the search for and treatment of the underlying causative illness. Any therapeutic plan that fails to include measures directed against the underlying cause is likely to be unsuccessful.

THROMBOTIC THROMBOCYTOPENIC PURPURA AND HEMOLYTIC–UREMIC SYNDROME

TTP and adult HUS appear to be similar disorders clinically—each presents with some of the elements of the classic pentad of thrombocytopenia, neurologic abnormalities, fever, and renal dysfunction. In TTP, neurologic abnormalities predominate, and renal dysfunction is seen less often; the opposite is characteristic of HUS. Pathophysiologically, however, they are distinct.

Most cases of TTP occur in previously healthy patients. Acquired idiopathic TTP is most often a single episode seen in older children and adults. TTP is also seen in association with the use of drugs such as ticlopidine, clopidogrel, cyclosporine, mitomycin, quinine, and combinations of chemotherapeutic agents. It also occurs concurrently with other conditions, such as pregnancy; autoimmune diseases; cancer; bone marrow transplantation; and bacterial and viral infections, including HIV and HTLV-1 (13–16). HIV was present in 4% to 50% of TTP cases in various series (17).

The pathophysiology of idiopathic TTP involves the formation of occlusive small vessel thrombi made up of platelets held together by unusually large von Willebrand factor (ULvWF) multimers with little or no fibrin. These large multimers are produced by and released from endothelial cells. Normally, a metalloprotease enzyme referred to as ADAMTS 13 cleaves these large multimers into smaller vWF molecules. This enzyme is synthesized in the liver and has a binding site on endothelial cells. During an episode of TTP, ADAMTS 13 activity is undetectable in the plasma, probably due to the action of IgG inhibitory antibodies. The lack of ADAMTS 13 activity leaves the ULvWF multimers uncleaved. Their large size and configuration induce active adhesion and aggregation of platelets, leading to thrombus formation which leads to the occlusion of

microvasculature. These clots are composed of aggregated platelets; fibrin is not detected in them.

In HUS, the toxin released from the causative *Escherichia coli* and *Shigella* strains is transported by neutrophils to target organs such as the brain and kidney where they cause endothelial damage. About 90% of cases of pediatric HUS are associated with *E. coli* enterocolitis (18). The toxin activates platelets and induces the secretion of ULvWF from the endothelial cells. However, unlike patients with TTP, those with HUS have normal metalloprotease activity and microthrombi in HUS contain fibrin and platelets with little or no vWF (17,19,20). Only smaller, not ultra-large, vWF fragments are found in the plasma of HUS patients (17). A prothrombotic state with biochemical evidence of thrombin generation and inhibition of fibrinolysis has been detected as early as the fourth day of diarrheal illness in children who go on to develop HUS (21).

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Although the pentad of symptoms and laboratory findings is considered classic in these diseases, it is important to realize that only about 40% of patients manifest all five criteria. There are no pathognomonic physical findings specific for TTP or HUS. In those with TTP, less than 15% have severe renal dysfunction with creatinine greater than 5 mg/dL (14,15). Only about one-third of HUS patients have neurologic dysfunction. Fever has been reported in approximately 50% of patients (22). Most patients with TTP present with vague symptoms of abdominal pain, nausea, vomiting, and weakness (23).

The most frequent initial neurologic abnormality is altered mental status, which may be manifested by subtle personality change, lethargy, agitation, or confusion. Seizures, hemiplegia, aphasia, paresthesia, and visual disturbances occur in less than half of patients and more often in the later stages of the disease.

Although 20% of patients may complain of gross hematuria, renal dysfunction is usually discovered only in laboratory studies. Bleeding, secondary to thrombocytopenia (e.g., epistaxis, hematuria, gastrointestinal or vaginal hemorrhage), is seen in about 30% to 40% at initial presentation. Anemia or thrombocytopenia may present as pallor, jaundice, or petechiae.

This type of multisystem symptomatology requires the EP to entertain a broad differential diagnosis that includes DIC, CNS infection, collagen vascular disease, bacterial endocarditis, eclampsia, HELLP syndrome, and malignant hypertension, among others. Laboratory studies can be very helpful in confirming the diagnosis of TTP or HUS, as the laboratory abnormalities of the pentad are more consistently present than the clinical symptoms.

ED EVALUATION

The patient's initial presentation will yield a broad differential diagnosis. The EP will begin their laboratory evaluation directed toward the etiology of fever, bleeding, and neurologic abnormalities. Complete blood count, platelet count, PT, PTT, fibrinogen, FDPs, D-dimer, lactate dehydrogenase, and examination of the peripheral blood smear often suggest the diagnosis. All patients with TTP–HUS are anemic; 90% have hemoglobin less than 10 g/dL, and 40% have less than 6 g/dL. The peripheral smear reveals schistocytes and a decreased number of platelets; 50% of patients have a platelet count less than 20,000/μL. The PT and PTT are normal in 90%, and fibrinogen is less than 100 mg/dL in only 5% of TTP–HUS patients. In DIC, by contrast, D-dimer and tests reflective of coagulation factor consumption are usually abnormal (15).

The LDH, blood urea nitrogen (BUN), creatinine, electrolytes, blood cultures, and CT scan of the head can provide further important diagnostic information. Lumbar puncture should be considered, but severe thrombocytopenia may lead the clinician to defer this procedure. Serum LDH is uniformly and greatly elevated in TTP patients; median levels are often six times normal. The

combination of a greatly elevated LDH, microangiopathic hemolytic anemia, and thrombocytopenia is often considered sufficient to make a diagnosis of TTP, even in the absence of fever and renal or neurologic abnormalities.

Abnormalities of BUN and creatinine are universal in patients in whom HUS is diagnosed, and are seen in 40% to 50% of patients with TTP.

KEY TESTING

- Complete blood count
- Comprehensive metabolic panel
- D-dimer
- International normalized ratio, PT and PTT
- Fibrinogen
- Lactate dehydrogenase
- HIV test
- Peripheral blood smear
- CT of the brain
- Lumbar puncture, if no contraindication

ED MANAGEMENT

As always, airway, breathing, and circulation should receive primary attention. In febrile patients in whom infection is suspected, antibiotic therapy should be initiated after obtaining appropriate cultures in the emergency department. The EP should be aware that despite significant thrombocytopenia and clinical bleeding, platelet transfusions are contraindicated in TTP (15). The exception to this is with patients with evidence of intracranial bleeding on CT where platelet transfusions are sometimes given as a stopgap measure.

The mainstay of current therapy for TTP is plasma exchange with FFP. Plasma exchange removes metalloprotease inhibitors and ULvWF and provides active ADAMTS 13 (13,24). The hematologist will determine infusion amounts and durations but will usually begin with an exchange of 1 to 1.5 plasma volumes per day (23).

Response to plasma therapy generally follows a predictable pattern in TTP. Neurologic abnormalities are the first to resolve, usually within 3 days where renal function may take 14 days to normalize. LDH levels normalize in about 5 days, and platelet counts in 10 days. It usually takes about nine plasmapheresis treatments to produce sustained improvement (25). Exchange therapy is generally continued for a minimum of 2 days after the platelet count returns to normal (23).

Prednisone in doses of 1 mg/kg/d or greater is often given on the basis of historic precedent (23). Patients who do not respond to plasmapheresis may be candidates for either splenectomy or cryopoor plasma (plasma with cryoprecipitate and therefore vWF removed).

Since the advent of plasma therapy, overall survival in patients with TTP has been about 90% (20). Recovery from neurologic, hematologic, and renal abnormalities is usually complete.

PEDIATRIC HEMOLYTIC&NDASH;UREMIC SYNDROME

E. coli O157:H7 is now recognized as the leading cause of HUS in the United States, Canada, and Europe (18). However, cases associated with other bacterial, viral, or fungal infections, HIV infection, chemotherapeutic agents, and radiation therapy continue to be reported.

E. coli O157:H7 is transmitted by contaminated food and water. Recently, there have been outbreaks related to frozen food products, organic spinach, and fast food establishments. Person-to-person spread is also reported in institutions, childcare centers, and within families (18).

Two to seven percent of children with *E. coli* O157:H7 infection develop HUS. HUS is usually evident 5 to 13 days after onset of the diarrheal illness. Most laboratory abnormalities resolve within 2 weeks. Twenty-five percent of patients will have severe HUS with more than 7 days of anuria, more than 14 days of oliguria, or stroke. Five to nine percent die, usually from thrombotic CNS involvement, which occurs in about 30% of pediatric HUS cases. Thirty-five to

fifty percent of survivors have chronic kidney damage; 3% have end-stage disease (18).

All patients should receive supportive care with careful management of fluids, electrolytes, and blood pressure, and dialysis when needed. Plasma exchange is generally reserved for those more severe cases that resemble TTP with CNS involvement (18,20). In patients with HUS secondary to Shiga-like toxins, there is no clear role for antibiotics or binding resins. Should these patients progress to end-stage renal disease, they become candidates for renal transplant, with a 10% recurrence rate. In contrast, patients with non–Shiga-like toxin-induced HUS, plasma exchange may be initiated by the hematologist accepting the patient.

CRITICAL INTERVENTIONS

- Avoid platelet transfusions in TTP–HUS except as a stopgap measure in patients with intracranial bleeding demonstrated on CT since administration of platelets is associated with deterioration in TTP–HUS.
- Involve hematology and nephrology services early when the disease process is suspected.
- In TTP, initiate plasma infusion with FFP and arrange for plasmapheresis.
- In HUS, carefully manage fluids and electrolytes.

DISPOSITION

Patients with TTP–HUS require high levels of nursing care and blood bank support, and should be admitted to an ICU. If plasmapheresis is not available, transfer to another institution should be arranged while plasma infusion therapy is begun.

Common Pitfalls

- Only about a third of patients have all five criteria of the classic diagnostic pentad of TTP–HUS at the time of presentation.
- Despite its rarity, TTP–HUS should always be considered in patients with neurologic, renal, or hemostatic abnormalities.

- The combination of microangiopathic hemolytic anemia, thrombocytopenia, an extremely high LDH, and normal PT/PTT is characteristic of TTP and distinguishes it from DIC.

CHAPTER 198

Complications of Antithrombotic Therapy

Michael Ganetsky

The antithrombotics have multiple life-saving indications and life-threatening complications. In acute coronary syndromes (ACS), venous thromboembolism, and acute ischemic stroke both treatment and prevention, the antithrombotics save lives. Patients may present to the ED with life-threatening complications related to outpatient use or develop iatrogenic complications while receiving antithrombotic therapy as part of ED care. Emergency physicians must understand the basic mechanisms, indications, and complications of antithrombotic therapy. This chapter provides a practical review of the complications of common antithrombotic therapy including the antiplatelet, anticoagulant, and fibrinolytic agents.

ANTIPLATELET AGENTS

Aspirin

Originally discovered by Hoffman in the late 1800s, aspirin remains the most effective, safest, and least expensive of all antithrombotic drugs. At doses as low as 75 mg, aspirin irreversibly blocks platelet synthesis of thromboxane A2, a potent inducer of platelet aggregation and vasoconstriction (1). Aspirin is commonly prescribed for the prevention and management of cerebrovascular and coronary artery disease and for the prevention of stroke in low-risk patients with atrial fibrillation or with contraindications to anticoagulant

therapy. Other indications include the treatment of pain, rheumatic fever, pre-eclampsia, and Kawasaki disease. Nonenteric-coated aspirin is rapidly absorbed in the stomach and inhibits platelet function within 1 hour versus 3 to 4 hours for enteric-coated. Antithrombotic effects last the 10-day life span of the individual platelet with 50% replacement of the platelet pool within 5 days (1). Given the significant benefit in ACS, occult gastrointestinal (GI) bleeding requires close monitoring but is not an absolute contraindication to aspirin therapy.

ADP Inhibitors

The thienopyridines, ticlopidine, clopidogrel, ticagrelor, and prasugrel selectively inhibit adenosine diphosphate (ADP)-induced platelet aggregation. Delayed onsets and significant side effects, such as thrombotic thrombocytopenic purpura and neutropenia, have limited the use of ticlopidine. FDA indications for clopidogrel include unstable angina, non-ST segment elevation myocardial infarction (NSTEMI), ACS with aspirin intolerance, and reduction of secondary atherosclerotic events in patients with recent MI, recent stroke, or peripheral vascular disease. Clopidogrel is commonly prescribed after stent placement with aspirin in the prevention of atherosclerotic disease (2). Prasugrel was approved by the FDA in 2009 and ticagrelor approved in 2011 as alternatives to clopidogrel for patients undergoing percutaneous coronary intervention (PCI) for ACS.

Glycoprotein IIb/IIIa Receptor Inhibitors

Studies of a rare bleeding disorder, Glanzmann thromboasthenia, led to the discovery of the glycoprotein IIb/IIIa receptor. Fibrinogen binding to the IIb/IIIa receptor is the “final common pathway” of platelet activation and aggregation. Several glycoprotein IIb/IIIa receptor inhibitors (GPI) have been developed within three broad categories; abciximab (ReoPro) is a monoclonal antibody, eptifibatide (Integrilin) is a synthetic peptide, and tirofiban (Aggrastat) is a nonsynthetic peptide. GPIs have been extensively studied and proven to be beneficial in patients with unstable angina

or NSTEMI undergoing PCI (3). Use in low-risk patients with unstable angina who are not undergoing PCI is not recommended. However, in high-risk patients in whom PCI is not possible, GPIs, specifically eptifibatide or tirofiban, may be considered in consultation with the admitting cardiologist.

ANTICOAGULANTS

Heparin

Heparin, derived from the Latin "hepar," meaning liver, was first discovered by McLean in 1916 from a liver extract. By inducing a conformational change in antithrombin III (ATIII), heparin produces a very rapid inhibition of thrombin (4). This complex inactivates several enzymes of the coagulation cascade's intrinsic system including IXa, XIa, and XIIa and highly sensitive enzymes of the common pathway Xa and IIa (thrombin). In addition, heparin inhibits platelet function and binds to endothelial cells. In contrast to fibrinolytics, heparin has no effect on clot already present but prevents new clot formation and existing clot propagation. Intravenous heparin is indicated in the ED for acute deep venous thrombosis (DVT), pulmonary embolism (PE), atrial fibrillation, and ACS. In hospitalized patients, intravenous heparin is used for those undergoing cardiac bypass, vascular surgery, or coronary angioplasty and for select patients with disseminated intravascular coagulopathy (DIC) (4). In contrast to warfarin, both heparin and low-molecular-weight heparin (LMWH) are safe to use in pregnancy as neither crosses the placenta.

Low–Molecular-Weight Heparins and Pentasaccharides

In the 1970s, work to improve heparin's anticoagulant effect while minimizing hemorrhagic side effects led to the depolymerization of heparin into fragments approximately one-third the size producing the LMWHs. Most unfractionated heparin molecules have the required long saccharide units needed to form a tertiary complex with ATIII and thrombin compared to only 25% of LMWH molecules (4). In addition, LMWH has less of an effect on platelet function and

vascular permeability, theoretically further reducing hemorrhagic complications. Clinical effects of these differences are summarized in Table 198.1.

TABLE 198.1
Clinically Significant Differences of Heparin and LMWH

Characteristic	Heparin	LMWH	Clinical Advantage
Nonspecific protein binding	High	Minimal	Improved consistency, safety, and decreased need for laboratory monitoring with LMWH
Dose response	Poor	Predictable	
Bioavailability	30%	>90%	
Platelet binding	More	Less	Theoretically decreased bleeding complications and HIT syndrome with LMWH
Inhibition of platelet function	More	Less	
Vascular permeability	Increased	No effect	
Half-life	30–150 min	12–24 hrs	Lack of therapeutic "Off Switch" and poor reversibility with LMWH
Protamine reversal	Good, predictable	Poor	

LMWH, low–molecular-weight heparin.

Multiple studies have compared LMWH to heparin in the management of ACS, DVT, and PE and have found it to be safe and effective (4). Outpatient enoxaparin has been shown to be safe, efficacious, and cost-effective when compared with inpatient heparin in the management of DVT (5). Enoxaparin is renally cleared and studies have shown that patients with a creatinine clearance less than 30 mL/min treated with standard dosing (1 mg/kg bid) have an increased risk of major bleeding; empirical dose reduction of 50% (1 mg/kg qd) reduces this risk (4).

The FDA has approved several LMWHs, each with unique pharmacokinetic profiles resulting from different depolymerization

techniques that prevent easy interchangeable use. Current FDA indications include acute management of DVT with or without PE with enoxaparin, outpatient DVT with enoxaparin, postsurgical DVT prophylaxis with enoxaparin or dalteparin, and unstable angina and NSTEMI with enoxaparin or dalteparin.

The minimum heparin fragment necessary for ATIII binding has been demonstrated to be a pentasaccharide; this led to the development of fondaparinux, a synthetic analog of the heparin ATIII-binding pentasaccharide. Similar to enoxaparin, it is administered subcutaneously and can be used for treatment of DVT, PE, and ACS (4).

Warfarin

In 1941, Link isolated dicumarol from moldy sweet clover that was later developed and marketed as a rat poison by the Wisconsin Alumni Research Foundation. Coumadin, the brand name of sodium warfarin, is the most commonly prescribed oral anticoagulant. Warfarin inhibits regeneration of the vitamin K cofactor required for hepatic carboxylation of factors II, VII, IX, and X and the anticoagulant proteins C and S. The coagulation cascade's extrinsic system and common pathway are thereby blocked. The relatively short half-life of the anticoagulant Protein C (6 to 8 hours) compared to the four coagulation factors (6 to 60 hours) results in an iatrogenic hypercoagulable state for 24 to 36 hours, necessitating anticoagulation with heparin or LMWH as a bridge while beginning therapy with warfarin (6). In addition to this hypercoagulable state, physicians must be aware of the dissociation of laboratory response and the clinical response to warfarin. Reduction in factor VII (half-life 6 hours) results in an increased international normalized ratio (INR) within 24 to 36 hours. However, a reduction in thrombin levels (half-life 60 hours) and hence a reduction in significant clot formation does not occur until the fifth day of warfarin therapy, necessitating continued effective anticoagulation with IV heparin or LMWH therapy during the initial 5 days of management of acute thrombosis (6).

Warfarin is most commonly indicated for the management of venous thromboembolism and prevention of embolism with prosthetic heart valves or atrial fibrillation. Warfarin is completely absorbed from the GI tract, achieving peak levels within 4 hours with a mean effective half-life of 40 hours. Adjustments in warfarin dosing are made based on the INR, a standardized measurement of prothrombin time (PT) that corrects for differing laboratory reagents. The typical therapeutic range is 2 to 3 for most indications with the exception of mechanical valves requiring a higher INR of 2.5 to 3.5. Frequent monitoring is necessary to determine the ideal dose in each patient as many factors such as age, use of other medications, diet, comorbidities, and even race may affect patient response. Table 198.2 provides a brief listing of factors that may increase or decrease the response to warfarin. Warfarin crosses the placenta and may cause multiple birth defects and spontaneous abortions, so it is categorized as class X in pregnancy.

TABLE 198.2
Factors that may Increase or Decrease INR/PT Response to WARFARIN

Increase	Decrease
Medications • Multiple antibiotics including azithromycin, cephalosporins, and fluoroquinolones, tetracyclines, metronidazole • NSAIDs including ibuprofen, indomethacin, celecoxib, naproxen, acetaminophen, and aspirin • Cardiovascular drugs including amiodarone, propranolol, streptokinase, TPA • Prednisone, cimetidine • Influenza virus vaccine **Alternative Medicine** • Ginkgo biloba, garlic **Diet** • Dietary deficiency or malabsorption of Vitamin K • Altered intestinal flora by antibiotics **Patient Factors** • Cancer, collagen vascular disease, congestive heart failure, diarrhea, hyperthyroidism, steatorrhea, advanced, age, liver disease, fever	**Medications** • Carbamazepine, haloperidol • Nafcillin, dicloxacillin, prednisone, ranitidine **Alternative medicine** • St. John's Wort **Diet Changes** • Excess dietary vitamin K **Patient Factors** • Edema, hereditary warfarin resistance, hyperlipidemia, hypothyroidism

INR, international normalized ratio; NSAID, nonsteroidal anti-inflammatory drug; PT, prothrombin time.

Direct Thrombin Inhibitors

Leeches were first used in the middle ages to rid the body of "black humors." Derived from a salivary extract of the leech *Hirudo medicinalis,* hirudin tightly binds to and inactivates thrombin. Currently used direct thrombin inhibitors (DTIs) include bivalirudin, argatroban, and dabigatran. DTIs inhibit both free and clot-bound thrombin and reduce platelet aggregating effects of thrombin. Dabigatran, an orally administered DTI, was approved by the FDA in 2010 for stroke prevention in patients with nonvalvular atrial fibrillation. Dabigatran has several advantages over warfarin: It has very few drug–drug and drug–food interactions and has a stable hematologic response thus not requiring frequent laboratory monitoring. Dabigatran has a fairly short duration of action

(elimination half-life of 12 to 17 hours), is predominately renally cleared, and a large portion can be removed via hemodialysis. In trials comparing dabigatran to warfarin, rates of major bleeding episodes tend to be similar, while dabigatran tends to cause less intracranial hemorrhages (ICHs) (7). Argatroban and bivalirudin are intravenous DTIs used in patients with ACS undergoing PCI or who have thrombotic complications and are at risk for or have confirmed heparin-induced thrombocytopenia (HIT) syndrome.

Factor Xa Inhibitors

Two orally administered direct factor Xa inhibitors have received recent FDA approval: rivaroxban in 2011 for stroke prophylaxis in patients with nonvalvular atrial fibrillation and in 2012 for treatment of DVT and PE; apixaban in 2012 for stroke prophylaxis in patients with nonvalvular atrial fibrillation. These factor Xa inhibitors are reversible and highly selective; they inhibit free and clot-bound factor Xa and prothrombinase activity without direct effect on platelet aggregation. Rivaroxaban has a short elimination half-life of 7 to 13 hours but factor Xa activity does not normalize for 24 hours after a dose. It is largely hepatically metabolized while one-third is renally excreted unchanged. Rivaroxaban has a predictable, dose-dependent anticoagulation effect; so routine monitoring of anticoagulation markers is not recommended. In clinical trials, bleeding rates are similar between rivaroxaban and enoxaparin (7).

Fibrinolytics

Streptokinase (SK) was the first fibrinolytic agent to be discovered by Tillett and Garner in 1932. The first use of fibrinolytics for reperfusion in acute MI was not reported until 1958 (8). Today's many different agents have one common mechanism: the conversion of plasminogen to plasmin, which then degrades fibrin and hence thrombus. First-generation, less fibrin-specific agents include SK, anistreplase, and urokinase. Second-generation, more fibrin-specific agents include recombinant tissue plasminogen activator (TPA;

alteplase) and several mutants of TPA including reteplase and tenecteplase (TNK-TPA).

SK is a purified preparation of a bacterial protein of group C β-hemolytic streptococci. SK binds to plasminogen, forming an activator complex that activates both fibrin-bound plasminogen and free circulating plasminogen producing localized thrombus breakdown and a generalized "systemic lytic state." Anistreplase is a modified SK molecule with a longer half-life (100 minutes) allowing for single-bolus dosing. IV or SQ heparin therapy is typically delayed 4 hours after SK and anistreplase to reduce bleeding complications.

Vascular endothelial cells produce TPA. Alteplase is a commercially produced recombinant TPA molecule. Alteplase has several advantages compared to SK, including increased fibrin specificity, resulting in less systemic fibrinolysis; a lower rate of allergic reactions; and an ability to lyse more highly linked fibrin clots, theoretically resulting in increased effectiveness in patients with prolonged symptoms. Reteplase is a deletion mutation of TPA with less fibrin specificity but a longer serum half-life of 18 minutes (vs. 5 minutes for recombinant TPA) allowing for bolus administration. No antigenicity has been reported with reteplase. Tenecteplase (TNK) is a triple substitution variant mutant of TPA with improved fibrin specificity and a longer half-life, again allowing bolus administration. Mortality benefits have not been demonstrated, but a significant reduction in bleeding with TNK compared to TPA was demonstrated in one study (8). Current indications for thrombolytic therapy includes ST-elevation MI (STEMI), acute ischemic stroke, and PE with signs of hemodynamic instability.

CLINICAL PRESENTATION

Patients with complications related to antithrombotic therapy may present to the ED in many different ways. Presentations may be occult, or dramatic, reported by the patient, or detected only during a meticulous history, physical examination, and workup. Regardless of the presentation, a high index of suspicion is necessary to rule out life threats in the patient on antithrombotic therapy.

GI bleeding is the major complication of aspirin therapy. Patients taking antiplatelet agents such as aspirin or clopidogrel may present with occult or massive GI bleeds. Although risk of bleeding is dose-dependent, bleeding may occur even with low-dose therapy.

Warfarin has been a main-stay of oral anticoagulant therapy for decades. Up to 15% of patients will suffer bleeding complications each year, 4.9% major bleeding complications, and up to 0.8% fatal, most commonly ICH (9). The risk of bleeding is directly related to the INR, increasing above 4, and is inversely related to the amount of time spent in the therapeutic range. Risk factors for bleeding include age greater than 75, past GI bleeding, hypertension, cerebrovascular disease, severe heart disease, renal insufficiency, alcoholism, known malignancy, and occult GI and genitourinary malignancies (10). Recent changes in drug doses, diet, and addition or discontinuation of other drugs may interact with warfarin, as described in Table 198.2.

Several types of skin lesions may result from anticoagulation therapy. The classic lesions of warfarin skin necrosis begin on the third to eighth day of therapy, resulting from capillary thrombosis in subcutaneous fat. Commonly associated with protein C deficiency, skin necrosis may also occur with protein S deficiency and in patients with normal levels. Unique skin lesions may occur with heparin and less commonly LMWH. An urticarial rash secondary to local histamine release is becoming less common owing to improved heparin purification techniques. Well-circumscribed plaques may occur at injection sites up to 20 days later, typically in obese or pregnant women. Heparin skin necrosis may occur within 1 day but typically at 1 week after starting therapy, often in patients without prior heparin exposure. The lesions start as an erythematous plaque before becoming hemorrhagic, necrotic, and often pruritic and painful. Biopsy often reveals antibodies, and thrombocytopenia may occur as part of the HIT syndrome (11). Skin necrosis with LMWH typically occurs in patients with prior heparin exposure, often without thrombocytopenia, and with fewer thrombotic complications.

In the ED, patients treated with antithrombotic medications require frequent re-evaluation. Minor bleeding, such as bleeding from puncture sites, or life-threatening GI or ICH must be detected and treated early to minimize further harm. For IV heparin, the risk of bleeding is $<6\%$ (10). Bleeding risk with heparin is directly related to dose and patient response as indirectly measured by the activated partial thromboplastin time (APTT). Dose adjustments based on every-6-hour APTT have been the traditional method of reducing hemorrhagic complications, but bleeding can occur even within the therapeutic range. Risk factors for bleeding complications include recent surgery or trauma, renal failure, aspirin use, GPIs, fibrinolytics, and age older than 70 years. LMWH has been associated with more bleeding complications after subcutaneous administration when compared with subcutaneous heparin and unusual bleeding episodes such as intrahepatic and psoas hematoma (11).

ED patients started on GPI or DTI may develop bleeding from vascular puncture sites, GI bleeding, or ICH, especially when treated with fibrinolytic therapy. Lower adjunctive heparin dose reduces the risk of bleeding with GPIs and fibrinolytics. Rates of life-threatening bleeding and intracranial bleeding for GPIs and DTIs are low as compared to fibrinolytics in ACS. Risk factors for bleeding from dabigatran include older age, baseline renal insufficiency, and acute kidney injury (7).

Patients started on fibrinolytic therapy in the ED may develop transient hypotension, mild-to-severe allergic reactions, and mild-to-life-threatening bleeding complications. In the absence of contraindications, risk factors for fibrinolytic-associated bleeding include older age, female gender, lower body weight, and hypertension.

ED EVALUATION

Many chief complaints are complicated by anticoagulation. The emergency physician should question the patient and family about the reason for anticoagulation, compliance with recent INR testing, other prescriptions, any potential recent medication adjustments, and over-the-counter and alternative medicines. Discussions with primary

care physicians and medical record reviews often help fill in historical blanks. The ED physician should also question the family about subtle changes in mental status, recent “minor falls,” or bleeding. Changes in vital signs may be evidence of early hemorrhagic shock or ICH. Hypertension may be secondary to Cushing response in ICH. Examine carefully for pallor, contusions, abrasions, ecchymosis, and other skin lesions. Perform a rectal examination with any suspicion of bleeding and in any patient beginning anticoagulation in the ED.

In patients with complaints related to antithrombotic therapy, check hemoglobin, platelets, PTT, INR, and other tests as indicated. Patients with bleeding related to aspirin therapy may have normal platelet levels but functional platelet deficits. Medication noncompliance, medication changes, diet factors, and concurrent illness may affect the adequacy of anticoagulation, necessitating laboratory screening in the ED.

GPI therapy may have mild or dramatic effects on platelet levels. Mild thrombocytopenia occurs in 5% of patients that are treated. Severe thrombocytopenia ($<$50,000) occurs in 2% of patients receiving abciximab versus 1% of eptifibatide and tirofiban. Acute profound thrombocytopenia ($<$20,000) occurs within 24 hours of administration of abciximab in 0.7% of patients but is rarer with eptifibatide and tirofiban. Platelet counts must be checked daily in patients receiving GPI to detect this rare but life-threatening complication (12).

Similarly, heparin and LMWH may have mild or dramatic effects on platelets. An early nonimmune-mediated transient thrombocytopenia occurs in 25% of patients, resolving in the majority within 3 days despite ongoing treatment. HIT syndrome develops in up to 3% of patients, typically presenting 5 days after initial heparin exposure but earlier in patients with prior exposure. The clinicopathologic syndrome is characterized by HIT antibody formation accompanied by a fall in the platelet count of $>$50% or skin lesions at injection sites. A hypercoagulable state may result in producing both venous and arterial thrombosis and DIC. The HIT antigen is platelet factor IV conformationally modified by interaction

with medium-chain heparin molecules accounting for the reduced incidence of HIT with low-molecular-weight shorter-chained heparins (11).

The DTIs and factor Xa inhibitors have various effects on coagulation parameters that impact on assessing degree of anticoagulation. Ecarin clotting time has a linear dose–response correlation with dabigatran; however it is not readily available. Thrombin clotting time is overly sensitive and the aPTT has a nonlinear response to dabigatran concentrations. Therefore, a normal thrombin clotting time or aPTT can be used to qualitatively exclude dabigatran-induced anticoagulation; however, when elevated, are not useful to determine degree of anticoagulation (7). The PT and HepTest are sensitive markers of the degree of anticoagulation with apixaban. For rivaroxaban, conventional PT/INR assays are not useful; anti-Factor Xa chromogenic assays or specialized PT assays with rivaroxaban calibrators are recommended and have recently become commercially available (13).

A low threshold for imaging of patients on antithrombotic therapy is required to detect occult but life-threatening bleeding. Even with minor mechanisms of blunt head trauma without loss of consciousness or blunt abdominal trauma without significant tenderness, head and abdominal computed tomography (CT) scans are recommended to diagnose occult life-threatening bleeding in patients on daily warfarin therapy (14,15).

For patients started on fibrinolytic therapy in the ED, repeat physical examinations are essential for the detection of bleeding. The majority of bleeding will occur at vascular puncture sites. Check laboratory values every 6 hours for 24 hours after therapy to detect occult blood loss. A fall in hemoglobin without an obvious source of blood loss necessitates a more diligent search. Repeat rectal examinations and a CT scan of the abdomen and pelvis may be necessary. Any change in mental status requires discontinuing therapy and an immediate head CT.

KEY TESTING

- CBC, serum chemistries (to assess for renal function)

- Type and screen/cross if transfusion of blood products is expected
- Routine coagulation studies (PT/PTT/INR)
- Focused coagulation studies and drug concentrations (i.e., thrombin time, bleeding time, ecarin clotting time, clotting factor concentrations, HepTest) are typically not routinely available nor are currently recommended to guide ED management
- Focused assessment of bleeding site (i.e., CT head, CT abdomen, GI consultation for endoscopy/colonoscopy)

ED MANAGEMENT

In the anticoagulated patient with bleeding, several factors must be considered. What is the severity of this bleeding episode? Is the bleeding into a closed space? Why is the patient on anticoagulation, and what is the risk of reversal? What other modalities such as endoscopy and proton pump inhibitors may be efficacious? If the risk of reversal is high (i.e., mechanical valve), can the patient be managed with just transfusions?

Patients with GI bleeding related to outpatient antiplatelet agents such as aspirin and clopidogrel require standard treatment including large-bore IV access, volume replacement and packed red blood cell replacement as indicated, proton pump inhibitor therapy, and specialty consultation for endoscopy. Despite normal levels, a functional platelet deficiency exists, requiring platelet transfusion of 5 to 10 U of random donor platelets to raise functional platelet levels by 50,000. Use of DDAVP (desmopressin), in addition to platelet transfusion, has been advocated for reversal of aspirin and clopidogrel. The standard dose is 0.3 to 0.4 μg/kg in 100 mL saline over 30 minutes (16). A summary of the management of bleeding complications from antithrombotic therapy is presented in Table 198.3.

TABLE 198.3
Management of Bleeding Complications Related to Antithrombotic Therapy

Aspirin or Clopidogrel	
Major[a]	Transfuse 5–10 U of random donor platelets to raise platelet levels by 50,000 DDAVP 0.3–0.4 μg/kg in 100 mL saline over 30 mis.
Glycoprotein IIb/IIIa Inhibitors	
Major or reversal for CABG	Abciximab: Discontinue all antithrombotics. Infuse 5–10 U of random donor platelets to raise platelet levels by 50,000 Eptifibatide and Tirofiban: Discontinue all antithrombotics. Platelets ineffective
Heparin	
Minor bleeding	Hold heparin Close observation and serial APTT
Major bleeding	Hold heparin Protamine 1 mg/100 mg of heparin in last 2–3 hrs
LMWH	
Major bleeding	Protamine 1 mg/1 mg of enoxaparin, 1 mg/100 U dalteparin, or 1 mg/100 U ardeparin Repeat protamine dosing often needed at 0.5 mg/1 mg of enoxaparin, 1 mg/100 U of dalteparin, or 1 mg/100 U ardeparin
Warfarin	
INR <4.5 without bleeding	Lower or omit next dose Recheck INR in 24–48 hrs
INR 4.5–10 without significant bleeding	Omit next one or two doses Recheck INR in 24 hrs Recent recommendations suggest against routine use of Vitamin K (17)
INR >10 without significant bleeding	Hold doses Vitamin K 2.5–5 mg PO Recheck INR in 24 hrs Resume therapy at lower dose once INR is at therapeutic level
Serious or life-threatening bleeding at any INR	Vitamin K 10 mg SLOW IV infusion FFP 2–4 U Consider PCC per hospital guidelines and in consultation with specialist, especially if intracranial or closed-space bleeding
Pentasaccharides	
Major	rVIIa 90 μg/kg; however routine use is still considered experimental
Direct Thrombin Inhibitors	
Major	Discontinuing therapy. No reversal agent is available, but half-life is short. Consider 2 U of FFP if suspect concomitant coagulation factor deficiency Factor VIIa is controversial but successful in some case reports. Dabigatran can be eliminated via dialysis so should be considered for life-threatening closed-space bleeding
Factor Xa Inhibitors	
Major	PCC have been shown to completely reverse rivaroxaban-induced prolongation of coagulation markers in health volunteers; however routine use is still considered experimental and should be balanced against prothrombotic risks of PCCs
Fibrinolytics	
Major bleeding	Start with 10 U of cryoprecipitate and 2 U of FFP Persistent bleeding or ICH: Above with 5–10 U of platelets and aminocaproic acid: loading dose of 5 g or 0.1 g/kg over 30–60 min followed by continuous infusion of 0.5 to 1 g/hrs

FFP, fresh-frozen plasma; PCC, prothrombin concentrate complex; rVIIa, recombinant factor VIIA.
[a]Major complications: life-threatening, ICH, or requiring blood transfusion.

Rapid reversal of GPI blockade may be necessary in patients who need emergent coronary artery bypass grafting or develop significant bleeding. Abciximab is a long-acting receptor blocker with 50% receptor blockade and platelet inhibition at 24 hours. Fortunately, the plasma half-life of the drug is only 15 to 30 minutes. Discontinuation of infusion and platelet transfusion are effective in reversing abciximab. Eptifibatide and tirofiban are competitive dose-dependent receptor blockers with return of normal hemostasis after only 4 hours. Reversal of these two agents requires discontinuation of the drug and time for clearance. With renal failure, hemodialysis

may be necessary. Platelet transfusion is of little use, as the high number of drug molecules will easily saturate new glycoprotein receptors on transfused platelets. Treatment of GPI thrombocytopenia includes discontinuation of the GPI and heparin and platelet transfusion (12).

Careful consideration must be given to the appropriate management of the anticoagulated patient even without bleeding. A subtherapeutic INR may require anticoagulation with heparin or LMWH while the warfarin dose is increased depending on the indication for warfarin. For the 50-year old with a mechanical valve who "ran out of warfarin a week ago" and now has an INR of 1, simply restarting warfarin may result in an iatrogenic hypercoagulable state and breakthrough thromboembolism. A supra-therapeutic INR may require little more than holding the next dose. Specific management depends on the degree of elevation, presence of bleeding, and the reason for anticoagulation. Methods to lower the INR include withholding or lowering the next dose, vitamin K (Phytonadione), and replacement products such as fresh-frozen plasma (FFP), prothrombin concentrate complex (PCC), or recombinant Factor VIIa (rFVIIa). The American College of Chest Physicians' evidence-based guidelines for the asymptomatic patients with an elevated INR are included in Table 198.3 (17). Major bleeding has not been clearly defined in the literature but for practical purposes may be considered to be any life-threatening bleeding, bleeding into a closed space, or bleeding requiring transfusion or surgical intervention.

Vitamin K is not without risk. A classic concern is anaphylaxis, which may occur at any dose when given IV and IM; however, anaphylaxis is very rare with modern preparations of Vitamin K (16). Subcutaneous absorption is unpredictable. Intramuscular administration may result in hematoma formation. Complete correction of the INR may result in breakthrough thromboembolism. High-dose vitamin K risks prolonged warfarin resistance and may precipitate thromboembolism for up to 1 week. Of the three routes, oral administration is considered the safest and most predictable, with effects beginning in 6 to 10 hours. Oral vitamin K (1 mg) lowers

an elevated INR between 4 and 10 in an asymptomatic patient more rapidly than 1 mg subcutaneously without an increased risk of thromboembolism (18). However, a randomized controlled trial did not find a difference in bleeding rates in nonbleeding patients with an INR between 4.5 and 10 treated with Vitamin K or placebo (19). Slow IV infusion over 10 minutes to prevent anaphylaxis is recommended only for life-threatening active bleeding with effects beginning in 1 to 2 hours. However, up to 24 hours may be needed for the full effects of Vitamin K, so doses typically need to be repeated and either FFP or PCC should be administered if immediate effects are desired. Vitamin K is not effective in advanced liver failure when coagulation factors are no longer synthesized.

The treatment of life-threatening bleeding related to warfarin requires administering vitamin K (10 mg) by slow IV infusion, along with factor replacement with FFP, PCC, or recombinant factor VIIa (rVIIa). Traditionally, 2 to 4 U of FFP are given for immediate control of bleeding; however, this may lead to volume overload, allergic reactions, and there is often a delay in thawing and delivering the blood products (13).

PCC provides a more rapid reversal of warfarin-associated coagulopathy than FFP and are recommended by many national guidelines (13). First used to treat hemophilia B, PCC is a fractionation product of FFP containing various amounts of factors II, VII, IX, and X. Long shelf-life and easy reconstitution into a highly concentrated volume (500 to 1,000 U/20 mL vs. 1 L of FFP per dose) allow for rapid and quick reversal without volume overload or infectious risk. Available PCCs include Bebulin VH, Profilnine, Octaplex, and Beriplex. However, until 2013 only 3-factor PCCs were available in the United States, which are less effective in reversing INR than the 4-factor concentrates. In 2013, the FDA approved Kcentra, a 4-factor concentrate marketed as Beriplex internationally for use in the United States. PCCs carry risk of thrombotic complications and DIC and are very expensive; therefore use should be limited to life-threatening bleeding (13). Also, outcome studies of PCC for ICH do not have control groups, so strength of evidence is mostly based on consensus. Emergency physicians should become

familiar with their hospital's availability of PCCs and guidelines for reversal of warfarin-associated bleeding as there is significant variability amongst institutions. rVIIA has also been shown to reverse INR value but not restore normal hemostasis in patients with warfarin-associated coagulopathy; therefore, PCCs or FFP are preferred agents (13).

Management of heparin-associated bleeding begins with stopping heparin therapy (half-life of 30 to 150 minutes for doses of 25 to 400 U/kg). With life-threatening bleeding, protamine may be used to reverse heparin anticoagulation in a dose of 1 mg/100 U of heparin administered in the previous 2 to 3 hours. As with vitamin K, there are risks associated with protamine administration. Hypotension, bradycardia, flushing, and fatal anaphylactic reactions have been reported. Dose is limited to 50 mg and must be given slowly over 10 minutes. As the duration from last treatment with heparin increases, heparin activity decreases, requiring less protamine for reversal. Although reversal is rapid, the half-life of protamine is shorter than heparin, necessitating repeat dosing if rebound bleeding occurs. In contrast to heparin, LMWHs cannot simply be turned off after subcutaneous administration. The long half-life must be weighed against the benefits when deciding on LMWHs versus heparin. The dose of protamine is compound-specific: 1 mg/1 mg of enoxaparin, 1 mg/100 U dalteparin, or 1 mg/100 U ardeparin. Repeat dosing is often needed at 0.5 mg/1 mg of enoxaparin, 1 mg/100 U of dalteparin, or 1 mg/100 U ardeparin. To date, only a few case reports of neutralization of LMWH have been published with relatively poor efficacy in comparison to heparin neutralization (11).

Management of HIT syndrome and warfarin skin necrosis includes discontinuing all heparin or warfarin products and administration of a rapid-acting anticoagulant such as danaparoid, a mixture of anticoagulant glycosaminoglycans with predominant antifactor Xa activity, or a DTI such as bivalirudin or argatroban.

Bleeding rates with the pentasaccharide fondaparinux are similar to enoxaparin. Use of rVIIa in healthy volunteers given fondaparinux will normalize prolonged coagulation parameters and there is anecdotal evidence of rVIIa controlling fondaparinux-induced

bleeding. The recommended dose of rVIIa is 90 μg/kg intravenously; however routine use is still considered experimental and further clinical experience is necessary before these can be recommended as standard of care (16).

Optimal reversal of the DTI dabigatran is still controversial and no effective reversal agent has been established. Given dabigatran's relatively short half-life, most bleeding episodes can be managed expectantly with supportive care and transfusion of red blood cells. However, closed-space bleeding (i.e., ICH) will likely not respond to this approach. Transfusion of FFP is controversial and is often recommended for repletion of any possible concomitant factor deficiency. Animal studies suggest rVIIa can decrease bleeding times from dabigatran. However, anecdotal experience with bleeding from the DTIs melagatran and lepirudin showed mixed results with rVIIa. In animals given dabigatran, PCCs have improved clotting time and bleeding, but in healthy volunteers given dabigatran, PCC did not reverse coagulation parameters (20). Given the thrombogenic risks of PCCs, routine use for reversal of dabigatran is not recommended. Dialysis can rapidly increase serum dabigatran elimination and thus, theoretically reverse the anticoagulated state. Dialysis may be an effective therapy for dabigatran-induced closed-space bleeding if it can be initiated quickly, but has not be studied clinically as of yet (13,16,21).

Factor Xa inhibitors such as rivaroxaban and apixaban are fairly novel and there is not much experience as of yet with reversal. In animal models, PCC has been shown to reverse anticoagulation induced by rivaroxaban (13) In healthy human volunteers given rivaroxaban, a single dose of PCC completely reversed prolonged coagulation markers (20). Therefore, PCCs seem the most promising reversal agent for Factor Xa inhibitors, but further clinical experience is necessary before these can be recommended as standard of care.

The best way to reduce complications from fibrinolytic therapy is to carefully review indications and contraindications before administration. Each institution should create protocols for STEMI, acute ischemic stroke, and massive PE with easy-to-follow pathway of indications, contraindications, patient consents, consultants to

notify, adjunctive medications, and treatment of complications. Avoid unnecessary procedures and blood draws. Nasal intubation and nasogastric tubes may precipitate massive epistaxis. Arterial lines are rarely essential for ED management. If central access is absolutely required, femoral vein cannulation is preferred as manual pressure of a missed jugular or a subclavian site and a chest tube for an iatrogenic pneumothorax are unnecessarily challenging.

The bulk of fibrinolytic bleeding will occur from puncture sites requiring only direct point pressure to the wound without discontinuing fibrinolytic therapy. Management of life-threatening GI bleeding requires aggressive volume replacement with crystalloid and packed red blood cells as indicated, reversal of fibrinolytic therapy, and adjunctive measures including proton pump inhibitors and endoscopy. Management of ICH requires cryoprecipitate, FFP, platelets, an antifibrinolytic agent, and neurosurgic evaluation. Most life-threatening hemorrhage related to fibrinolytic therapy responds to the administration of 10 U of cryoprecipitate and 2 U of FFP (22). With persistent bleeding or ICH, administer 5 to 10 U of platelets and an antifibrinolytic agent such as aminocaproic acid with a loading dose of 4 to 5 g or 0.1 g/kg over 30 to 60 minutes followed by continuous infusion of 0.5 to 1 g/hr until bleeding is controlled. Be careful to avoid antifibrinolytics in the patient with DIC.

With either SK or anistreplase, allergic reactions may occur typically with mild symptoms of chills, fever, and rigors but in severe forms may include anaphylaxis. Treat with standard therapy including antihistamines, epinephrine, steroids, and airway management. Although controversial, repeat dosing or readministration within 1 year is not recommended (8). Hypotensive episodes secondary to bradykinin generation respond well to decreasing rate of infusion, vasopressors, and IV fluids.

CRITICAL INTERVENTIONS

- Inquire about recent changes in drug doses, diet, and addition or discontinuation of other drugs that may interact with warfarin.
- Maintain a low threshold for imaging the head or abdomen in patients with minor trauma on antithrombotic therapy to detect

occult, but life-threatening, bleeding.
- Administer reversal agents for major bleeding complications associated with antithrombotic therapy (Table 198.3).

DISPOSITION

Most patients who present with or develop complications related to antithrombotic therapy will require hospitalization, especially if they have signs of active bleeding. They will typically need monitoring of hematocrit, coagulation factors, and extent of their bleeding. They may need endoscopic or surgical intervention dependent on the site of bleeding. They may also need replacement of significant blood loss or reversal of anticoagulation dependent on which agent they are taking.

The sub-therapeutic patient on warfarin often requires adequate anticoagulation with heparin or LMWH to prevent a paradoxical hypercoagulable state and breakthrough thromboembolism. Outpatient enoxaparin therapy followed by increased warfarin with close follow-up prevents unnecessary hospitalization.

The asymptomatic patient with a supra-therapeutic INR need not be an automatic admission for "coagulopathy." Although the rate of serious bleeding increases with an INR >4, the overall rate remains low. The indication for anticoagulation, reason for supra-therapeutic level, underlying comorbidities, overall risk of bleeding, fall risk, social situation, reliability, and availability of follow-up must all be considered. Holding warfarin doses, discharge to home, and repeating an INR in the next 24 to 48 hours are typically sufficient for patients with good follow-up who are not at increased risk of falling. HIT syndrome and skin lesions require admission for anticoagulation with alternative agents in consultation with a hematologist.

Anticoagulated patients with bleeding may have an underlying disorder that has been unmasked by the anticoagulant. GI or GU bleeding after starting anticoagulation requires aggressive evaluation for malignancy. Up to 25% of these patients will have an otherwise occult malignancy detected during evaluation for anticoagulant-related bleeding.

For the asymptomatic anticoagulated patient with minor trauma, therapeutic INR, stable hemoglobin, normal imaging studies, and reliable caretakers, discharge with close follow-up is appropriate. The symptomatic anticoagulated trauma patient with evidence of active bleeding requires aggressive management including reversal of anticoagulation, blood replacement, early surgical consultation for operative intervention, and hospitalization. These patients often require transport to a level-one trauma center after initial stabilization for definitive care.

Patients treated with fibrinolytic therapy require admission to an intensive care unit for treatment of the primary disease; close observation and treatment of complications; and cardiology, neurology, and/or neurosurgery consultation.

Common Pitfalls

- Failing to ask about anticoagulation; indication for, changes in dose, timing, and result of last INR, compliance, bleeding or skin lesions, comorbidities, new medicines, changes in diet, and changes in mental status or back pain.
- Failure to realize a patient's medication is actually an anticoagulant or specifically ask about novel anticoagulants. There has been a significant number of oral anticoagulants and antiplatelet agents recently approved by the FDA (i.e., dabigatran, rivaroxaban, apixaban, prasugrel, ticagrelor) and clinicians must add these to their mental list of medications that increase bleeding risk when evaluating a patient with trauma or bleeding.
- Inappropriate use of vitamin K, protamine, or PCCs. These have serious potential complications. High-dose vitamin K may result in prolonged warfarin resistance for up to 1 week. PCCs carry risk of thrombotic complications and DIC and are very expensive.
- Clinicians should become familiar with their institution's guidelines on reversal of anticoagulation. Many institutions are adopting use of PCCs for warfarin-induced life-threatening bleeding and the clinician should learn ahead of time which product is available and the recommended dose.

- The safest place for an asymptomatic supra-therapeutic patient may be at home "resting on their couch." Decide on admission versus close follow-up on a case-by-case basis in consultation with the patient's primary physician.
- The patient with a mechanical valve who ran out of warfarin a week ago with an INR of 1 cannot simply be sent home with a "little extra" warfarin. Adequate anticoagulation with heparin or enoxaparin is necessary in conjunction with restarting warfarin.

CHAPTER 199

Sickle Cell Disease

Michele L. Dorfsman and Donald M. Yealy

Sickle cell disease (SCD) is a hereditary disorder due to a genetic mutation in the hemoglobin protein. Hemoglobin S (for “sickle”) differs from the normal hemoglobin A in that valine is substituted for glutamic acid in position 6 of the globin beta chain. Both hemoglobin A and C function similarly in the oxygenated state, but deoxygenated hemoglobin S tends to polymerize leading to red cell sickling. Erythrocytes with less total hemoglobin or less hemoglobin S are more resistant to sickling, as are younger and small cells.

Individuals who are homozygous for the sickle cell gene (SS) have *SCD*. Their erythrocytes contain at least 90% hemoglobin S. Patients who are heterozygous for the sickle cell gene (SA) have *sickle cell trait*. Their erythrocytes contain both hemoglobin A (50% to 60%) and hemoglobin S (30% to 40%). *Common sickle variants* include *SC disease* (in which patients are heterozygous for both hemoglobin S and hemoglobin C which is caused by a different mutation of the beta globin chain) and *sickle-thalassemia*. These variants display lower red blood cell (RBC) levels of hemoglobin S and are associated with less morbidity than SCD. Most patients with sickle trait or variants have a normal life span and rare crises, although there is an increased risk for sudden death during exertion (1).

The anemia of SCD is due to both chronic and acute hemolysis. The red cell membranes are damaged with repeated episodes of sickling. During an acute painful vaso-occlusive crisis (VOC), the involved red cells undergo sickling. Initially, this may be reversible, but eventually the RBCs become irreversibly sickled and are destroyed. Sickled cells slow and obstruct the microvascular

circulation, compounded by the increased viscosity and the increased endothelial adherence of RBCs. Local tissue ischemia and acidosis lead to further sickling, and ischemic organ damage occurs.

The clinical severity of SCD is variable. Some patients follow a mild clinical course with infrequent VOCs, but others are more severely affected. An increased frequency of painful crises, particularly chest crises (see later), is associated with a shorter life expectancy (1). Most homozygous patients develop painful events before the age of 1 year, and by 5 years nearly all patients have experienced a VOC. Sickle cell patients diagnosed with concomitant asthma have an increased SCD morbidity and mortality (2).

Infection is a leading cause of mortality in patients with SCD. The life expectancy of these patients is increasing because of aggressive medical therapy, particularly treatment of infection. Currently, most sickle cell patients survive into middle adulthood (1). Sickle trait, SC, and sickle-thalassemia patients all have near normal life expectancies and suffer far fewer symptoms.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Painful VOCs are the most common presenting problem for sickle cell patients in the emergency department (ED). Many triggers have been identified, including infection, systemic acidosis, dehydration, hypoxia, cold exposure, pregnancy, and physical or emotional stress. Episodes of painful sickle events commonly last 48 hours to several days. Notably, many patients who present have an exacerbation of a long-standing pain syndrome—perhaps caused by previous ischemia and organ damage—but less triggered by acute sickling, though this is hard to distinguish from a VOC.

Bony pain is very common during acute VOCs. Adults usually complain of back and proximal extremity pain (2,3). When evaluating a patient with suspected bony VOC pain, other causes, such as trauma or infection, must be considered. The association between sickle cell anemia and *Salmonella* osteomyelitis is well described, yet *Staphylococci* remain the most common pathogen

causing osteomyelitis. Repeated episodes of bony ischemia can lead to aseptic necrosis, particularly in the femoral head (4) and carpal navicular areas, causing persistent pain frequently mistaken for acute vaso-occlusion.

Abdominal pain, nausea, and vomiting are common with episodes of vaso-occlusion. Local ischemia is thought to be the cause of these symptoms. However, a careful evaluation to rule out other causes of abdominal pain is mandatory in these patients. Because of the persistent hemolysis, sickle cell patients develop calcium bilirubinate gallstones and symptomatic cholelithiasis. In addition, other causes of acute abdominal pain, including pancreatitis, appendicitis, renal colic, and peptic ulcer disease should be considered before concluding that a vaso-occlusive event is the sole cause. The presence of active bowel sounds and a lack of high fever or signs of peritonitis favor a nonsurgical etiology. The risk of infectious hepatitis is higher in older sickle cell patients if they have received previous transfusion therapy or injected drug abuse. Jaundice does not necessarily indicate liver disease, as it is commonly due to chronic hemolysis.

The pregnant sickle cell patient with abdominal pain is a diagnostic and therapeutic challenge. Identifying appendicitis or cholecystitis is more difficult because of the anatomic changes associated with pregnancy. Pre-term labor, placental ischemia and abruption, and spontaneous abortion are also more common in sickle cell patients than in the general population.

Low-grade fever during a vaso-occlusive episode is common; however, when the temperature exceeds 38°C, seek an infectious source. Viruses account for most infections, but because of functional asplenia, these patients are at a higher risk than others for localized bacterial infection or bacteremia, especially with encapsulated organisms such as *Streptococcus pneumoniae* and *Haemophilus influenzae.* The functional asplenia of sickle disease is due to autoinfarction of the spleen, which is usually completed by school age in those with homozygous disease. Patients with sickle trait or sickle cell variants generally have normal splenic function and immunity.

The *acute chest syndrome* (ACS) is a leading cause of death in patients with SCD. Patients with ACS present similarly to those with pneumonia. They have fever, chest pain, cough, and hypoxia and have new infiltrates on chest x-ray. Although the exact cause is unknown, ACS is thought to be caused by many mechanisms, from infection and fat embolism from infarcted bone to pulmonary microvascular sludging and infarction. The most common infectious etiologic agents of ACS are *Chlamydia pneumoniae, Mycoplasma pneumoniae,* and respiratory syncytial virus (5).

Chest pain is common in vaso-occlusive events (1). Sickle cell patients have a higher frequency of hypercoagulable diseases and thrombotic events, including pulmonary embolism and infarction. Thus, pleuritic pain can be due to vaso-occlusion (red cell micro-occlusion) with or without pulmonary infarction (platelet and coagulation protein-based clot) or due to infectious etiology. A productive cough, high fever, elevated total and immature neutrophil count, or Gram stain evidence of infection supports the diagnosis of pneumonia. The best clinical indicator of infarction is the absence of these infectious clues and the presence of occlusive symptoms in another area. *S. pneumoniae* and *H. influenzae* are the most frequent causes of bacterial pneumonia in sickle cell patients. It is also important to remember that in adults, chest pain can result from myocardial ischemia.

Focal or generalized neurologic signs and symptoms (including seizures) can follow vaso-occlusion in the cerebral circulation, with both small and large vessels affected. Acute retinal ischemia with visual loss and “floaters” from vitreous hemorrhages secondary to vessel disruption are also reported in sickle cell patients.

Priapism is a manifestation of local sequestration and vaso-occlusion and may present in all age groups. It often responds to vigorous medical therapy, including hydration, analgesia, local ice packs, or exchange transfusions. In refractory cases, surgical decompression is indicated. Testicular or ovarian ischemia can also result from vaso-occlusion, presenting with pain in the affected area.

Besides painful VOCs, the patient with SCD is subject to other less common episodic hematologic crises. These include sequestration,

hemolytic, megaloblastic, or aplastic crises. In *sequestration crisis,* acute anemia, hypotension, and potential shock occur because of sequestration of RBCs in the spleen. This often follows a viral illness and usually occurs in older adults with sickle cell variants. *Hemolytic crisis* can occur during a fulminant vaso-occlusive episode when large numbers of irreversibly sickled cells are lost. Severe anemia with increased reticulocytosis and jaundice is found. Marrow failure, resulting from either *megaloblastic crisis* (often from folate deficiency) or *aplastic crisis,* presents with a gradually falling hematocrit and deficient reticulocytosis.

In addition to the organ ischemia induced by RBC sickling, SCD patients frequently have enhanced coagulation, leading to arterial and venous thrombotic events. This is due to a variety of procoagulant syndromes seen more often in these patients, including protein C and S deficiency and circulating antiphospholipid antibodies (6).

ED EVALUATION

The diagnosis of an uncomplicated VOC is one of exclusion but common; a dangerous error is to attribute all pain in sickle cell patients to this cause. The initial investigation should seek evidence of an acute infection or other precipitating events. Chest pain can result from ACS, pneumonia, pulmonary embolism, pulmonary infarction, or myocardial ischemia; abdominal pain may reflect a surgical emergency. By the third decade of life, many sickle cell patients have undergone cholecystectomy and appendectomy, either because of demonstrable pathology or because abdominal pain during a previous vaso-occlusive crisis suggested an acute abdominal emergency. This eases the task of evaluating later episodes of acute abdominal pain by eliminating certain possibilities.

A focused history and examination are the cornerstones of the evaluation of sickle cell patients. Knowledge of the frequency and severity of past pain events and complications, the medication

history, and baseline laboratory values are helpful in tailoring the initial evaluation and treatment of patients with acute pain.

A complete blood count (CBC) and reticulocyte count (RC) are commonly ordered in sickle cell patients presenting for ED care. These can help screen for marrow failure, sequestration crisis, or infection. However, in a clinically uncomplicated VOC that is similar to previous episodes, these tests add little to the clinical management. In other patients, especially those with suspected infection or nonocclusive crisis, the CBC and RC can aid evaluation.

Most sickle cell patients have a persistent mild leukocytosis and a moderate anemia. The total leukocyte count is best adjusted for nucleated RBCs to avoid factitious elevation. Because of ongoing hemolysis and anemia, the RC should be elevated (usually to 8% or greater) compared to normal subjects. An abrupt drop in the hematocrit suggests a sequestration or hemolytic crisis, whereas an abnormally low RC suggests marrow failure.

Screen the urine for evidence of infection or infarction in patients with fever, pelvic, or back pain. If symptoms of urinary tract infection are present with pyuria or bacteriuria, obtain a urine culture in these immunocompromised patients to help guide follow-up therapy.

Fever, chills, or any pulmonary symptoms or signs suggesting a new abnormality mandate chest radiography to identify ACS or pneumonia. Because of the risk of bacteremia and sepsis, blood cultures should be obtained when there is evidence of pneumonia or pyelonephritis or when high fever or leukocytosis occurs without an apparent source.

Other tests may have a role depending on the clinical presentation. An electrocardiogram can aid when chest pain or other symptoms suggestive of myocardial ischemia exist. Serum electrolytes, blood urea nitrogen, and creatinine determinations can help assess hydration and renal function, but are not mandatory in clinically uncomplicated VOCs. In cases of unexplained abdominal pain, a serum amylase, lipase, liver enzymes, abdominal x-rays, gallbladder ultrasound, or CT scan may be indicated. Helical CT can help detect pulmonary embolism in patients in whom pneumonia or

vaso-occlusion do not explain the findings. A D-dimer is not usually helpful in given the high propensity of false-positive results.

In those patients with stroke, myocardial ischemia, pulmonary embolism, or other arterial/venous thrombotic findings, many begin an evaluation for hypercoagulability, beginning with prothrombin and partial thromboplastin time tests plus other specific tests for coagulopathies though these are not needed in other sickle crises and do not alter ED management.

An assessment of oxygen saturation is important, especially if any pulmonary or chest symptoms or abnormal physical examination findings exist. Arterial blood analysis is reserved for those with a suspected acid–base abnormality, inadequate oximetry signal, or severe hypoxemia (as a confirmatory test).

KEY TESTING

- CBC and RC if concern about worsening anemia
- Urinalysis if fever, abdominal, or back pain
- CXR if fever/chest complaints
- Pulse oximetry

ED MANAGEMENT

In unstable patients, airway and circulatory assistance are the primary immediate concerns. Once addressed, routine ED management can proceed with a diagnostic workup based on the previous recommendations. Treatment is usually supportive, as definitive treatment of vaso-occlusive pathophysiology is still lacking. The best treatment is rehydration with analgesia.

The choice of fluids is controversial; those with orthostasis or hypotension should receive isotonic solutions. In the absence of significant volume depletion, hypotonic fluids may have theoretical benefits. There are no clinical outcome data to support routine parenteral hypotonic solutions in VOCs. Irrespective of the fluid chosen, it is important to pay attention to the total volume administered to avoid iatrogenic pulmonary edema.

Traditionally, all sickle cell patients received supplemental oxygen during painful crises. Although oxygen reverses some sickling in vitro, it can depress erythropoietin levels and reticulocytosis, potentially interfering with a natural compensatory response (7). Currently, there are no outcome data supporting or refuting the routine use of oxygen, although pragmatism suggests that those with clinically important hypoxemia may benefit. An ambient oxygen saturation of $<90\%$ or a drop of $>5\%$ from known baseline is often used to initiate therapy.

Achieving adequate pain control in VOCs is challenging. By late adolescence, many patients with sickle disease require opioid analgesics to gain relief. Complicating the management of these patients are physician and nursing fears of drug abuse and secondary gain. Subjectively reported pain is generally the only tool available to measure discomfort; it is not possible to reliably identify "feigned" pain on clinical grounds or to separate VOC pain from an exacerbation of a long-standing pain syndrome. Optimal treatment of vaso-occlusive pain is based on multifaceted, inexpensive regimens that offer the best chance of timely relief with a minimum of complications. In addition, the patient must be educated to actively participate in the process of pain relief rather than reinforcing a passive approach. This means a frank discussion about the goals of therapy (pain relief, although not always immediate pain extinction, without harm) and the need for nonpharmacologic adjuncts including counseling and behavior modification. Therapy must be individualized based upon patients' previous clinical experiences (8).

Oral analgesics are the mainstays for most patients with mild to moderate pain, with parenteral regimens reserved for those who cannot tolerate oral agents or who are in severe pain. Most patients presenting for care in the United States receive opioids in addition to hydration and acetaminophen. Because the pain of vaso-occlusion is incited by ischemia, the analgesic effects of nonsteroidal anti-inflammatory drugs (NSAIDS) are less prominent than in other syndromes wherein prostaglandin excess is the major biochemical trigger (9). In addition, the risk of renal failure may be higher than

in non–sickle cell patients. A single NSAID dose is unlikely to cause harm, however, and can provide some additional analgesic effect.

Hydrocodone, oxycodone, morphine, and hydromorphone are good opioid choices for those with refractory or more intense pain. For those who require parenteral therapy, the key is choosing an adequate dose and regimen based on individual patient response; the ceiling dose is whatever relieves pain or causes side effects. Many of these patients have tolerance and require high doses of morphine or hydromorphone; conversely, treating all with high doses risks respiratory depression if opioid exposure has been rare. Intravenous regimens (either by repeated injections, continuous infusion, or patient-controlled administration) offer ease of titration, rapid analgesia, and less risk of side effects. Intramuscular injections should be rare and reserved for selected cases when oral therapy is impractical and venous access unobtainable.

A minority of sickle cell patients are opioid abusers. This has led some centers to initiate “contracts” with their patients in an effort to limit abuse while ensuring prompt and humane treatment when a painful crisis occurs. Commonly, the patient agrees in writing to take oral opioids only for severe pain and to contact a designated physician and ED during a crisis. The patient also agrees not to seek alternate opioid sources. This provides adequate care while limiting the total amount of opioid prescribed over a specified period.

For documented or suspected bacterial infections, a broad-spectrum antibiotic should be administered early. Sickle cell patients should take folic acid supplements daily to avoid megaloblastic crisis.

Transfusion therapy is indicated in selected sickle syndromes. In patients with priapism or aplastic, sequestration, or hemolytic crisis, exchange transfusion is preferable to simple transfusion to avoid the risk of iron overload and is generally more effective. Anemia alone is not an indication for emergency transfusion in the absence of signs or symptoms of deficient oxygen delivery to the heart or brain.

Some longer-term approaches to the treatment of SS disease are available. Hydroxyurea disrupts RBC endothelial adhesion, enhances hemoglobin F production, promotes the formation of hemoglobin S

polymers, may mediate nitric oxide release (see further), and can diminish the frequency and severity of crises (10,11). The long-term safety of this treatment is still not completely defined, with marrow failure a limiting side effect, and the drug has mutagenic and carcinogenic properties. It may also cause nausea, vomiting, and skin rashes. Hydroxyurea therapy can decrease mortality in patients (12). To date, bone marrow transplant remains the only curative therapy for sickle cell disease.

Inhaled nitric oxide may increase the oxygen affinity of hemoglobin S in humans both in vivo and in vitro. Therapeutic inhalation is thought to exert direct effect on the pulmonary vasculature to increase oxygenation through diminished shunting and reduce pulmonary hypertension (13). Clinical experience is limited, and its long-term efficacy and toxicity are unknown. It has been found to provide pain relief, especially with chest syndromes, when used with standard therapies but remains investigational (14).

CRITICAL INTERVENTIONS

- Seek evidence of an acute infection or another precipitating event in patients with vaso-occlusive events.
- Rehydrate and treat VOC pain using oral regimens rather than parenteral, when possible.
- Initiate broad-spectrum antibiotics for documented or suspected bacterial infection.

DISPOSITION

Patients with uncomplicated VOCs who are adequately hydrated and obtain sufficient pain relief in the ED can be discharged with close follow-up. There is no absolute rule to determine how long an “adequate” analgesia and hydration trial in the ED should be. If pain relief is obtained in uncomplicated VOCs, oral analgesics can be prescribed for 3 to 5 days to treat milder recurrence, a common phenomenon. Each patient should be encouraged to obtain further care from the same institution or a single physician (or group) to ensure continuity.

The inability to control pain is the most common indication for admission in adults. Patients with proven or suspected sequestration, aplastic, or hemolytic crisis require admission. The presence of any new neurologic sign or symptom, priapism, or an acute abdomen also mandates hospitalization.

In general, the presence of an invasive bacterial infection mandates admission, because it is largely through the aggressive treatment of infections that the life expectancy for SS patients has been increased. The exception would be that adults with a minor pharyngeal or respiratory tract infection may be discharged with treatment if close outpatient follow-up within 24 hours can be arranged (15). Besides these specific instances, admission is indicated for patients with fever, unexplained leukocytosis (especially with immature forms), or uncertain compliance with follow-up schedules.

A new alternative is use of a daytime care center to deliver fluids and analgesia under physician guidance and with nursing staff, akin to oncology outpatient infusion care; these are often adjacent to the ED or hospital and can serve to limit admission.

Finally, patients should be counseled to avoid any sympathomimetic drugs (including over-the-counter decongestants and illicit cocaine) and alcohol (which may suppress a stressed marrow). Pneumococcal and influenza vaccines can be offered or made available in follow-up, along with potential long-term oral penicillin prophylaxis for those with frequent bacterial infections.

Common Pitfalls

- Do not assume that abdominal pain is due to a vaso-occlusive event without considering other causes.
- Be careful not to overlook pneumonia or pulmonary infarcts in sickle cell patients.
- Osteomyelitis and aseptic necrosis of bone can be mistaken for “crisis” pain in this population.
- Exchange transfusion therapy is often not started early enough in the setting of neurologic changes or priapism.

- Give sickle cell patients with pain the benefit of the doubt while being prudent with the total number of doses of pain medication. In those with frequent visits, develop a clear plan to be used by all ED providers, and have the patient enter into a written treatment contract with the primary care provider, if possible.
- Educate sickle cell patients about avoiding triggers, maintaining hydration, and initiating early self-titrated analgesia to limit the need for recurrent ED visits.

CHAPTER 200

Anemia

Melissa A. Tscheiner

Anemia is defined as a decrease in the number of circulating red blood cells, with a concomitant decrease in the capacity of the blood to carry oxygen to tissues. Anemia is a manifestation of disease rather than a diagnostic entity in and of itself.

Anemia can be classified into disorders of decreased red cell production, disorders of increased red cell destruction, and anemia resulting from blood loss (1–3). Each of these diagnostic groups has its own clinical presentation and differential diagnosis (Table 200.1) and, in general, requires its own approach to emergency department (ED) evaluation and management.

TABLE 200.1
Differential Diagnosis of Anemia

Anemia Secondary to Blood Loss (Acute or Chronic)

Intraperitoneal

Retroperitoneal

Pelvic

Urinary tract

Gastrointestinal tract

Gynecologic (vaginal bleeding, placenta previa, abruption)

Epistaxis

Hemoptysis

External bleeding

Drug-related (coumadin, heparin)

Traumatic

Anemia Secondary to Decreased RBC Production (Insidious-Onset, Decreased Reticulocyte Count)

Hypochromic/microcytic

Iron deficiency

Thalassemia

Sideroblastic (including lead)

Chronic disease (infection, chronic inflammation, neoplasm, diabetes, liver failure, uremia, thyroid disease)

Macrocytic

Hypothyroidism

Folic acid deficiency

Chemotherapy, radiotherapy, immunosuppressive therapy

Liver disease

Vitamin B_{12} deficiency

Scurvy

Normocytic

Primary bone marrow disorder (aplastic anemia, myeloid metaplasia, myelofibrosis, myelophthisic anemia)

Secondary bone marrow disease (endocrinopathy, uremia, chronic inflammation, liver disease, ethanol ingestion)

Anemia Secondary to Increased RBC Destruction (Increased Reticulocyte Count, Free Hemoglobin, RBC Fragmentation)

Intrinsic

Enzyme defect (G6PD, pyruvate kinase)

Membrane abnormality (spherocytosis, elliptocytosis, spur cell, paroxysmal nocturnal hemoglobinuria)

Hemoglobin abnormality (hemoglobinopathy, thalassemia)

Extrinsic

Immunologic (alloantibody, autoantibody, cold agglutinins [e.g., mononucleosis])

Neoplastic (especially leukemia, lymphoma)

Collagen vascular (lupus, rheumatoid arthritis, periarteritis nodosa)

Infections (mycoplasma, syphilis, malaria, Bartonella, viral)

Other (thyroid disease, ulcerative colitis)

Mechanical (microangiopathic hemolytic anemia, prosthetic valve)

Abnormal sequestration (hypersplenism)

Environmental (drugs, toxins, hyperthermia, drowning)

RBC, red blood cell.

Anemia of any cause may present acutely or chronically, and the aggressiveness of intervention and management depends on the acuteness of onset and on the severity of the clinical presentation. For example, anemia secondary to acute gastrointestinal blood loss may require vigorous fluid resuscitation, transfusion therapy, and intensive care management; anemia secondary to chronic occult gastrointestinal bleeding leads to a well-compensated iron-deficiency anemia that can be evaluated and treated on an outpatient basis (4,5).

Defective red blood cell production may be due to interruption in the availability or synthesis of any of the three moieties of the hemoglobin molecule: iron, heme, and globin. Hence, anemia may result from iron deficiency, from toxins or enzymatic deficits that interfere with heme synthesis, or from genetic defects in globin synthesis. Disorders and deficiencies that affect the proliferation of erythroid stem cells in the bone marrow may also result in anemia from decreased red cell production (6–8).

Red cell destruction may result from either intrinsic or extrinsic causes. Intrinsic abnormalities of hemoglobin, enzymes, or red cell membranes may result in hemolytic anemia. Extrinsic destruction may be due to immunologic, mechanical, or environmental causes or to hypersequestration (hypersplenism) (1–3,8).

Blood loss resulting in anemia may be acute or chronic and may originate from intraperitoneal, retroperitoneal, pelvic, pleural, gynecologic, or gastrointestinal sources (3).

CLINICAL PRESENTATION

Patients with anemia secondary to acute blood loss present with hypovolemia. A source of blood loss may be readily identifiable on clinical evaluation; menstrual and gastrointestinal tract blood loss are the most common reasons for occult bleeding (9). A history of underlying disease (e.g., cirrhosis, bleeding diathesis, malignancy, or infection) or of medication use (e.g., use of salicylates, nonsteroidal anti-inflammatory drugs, or anticoagulants) may be

useful in guiding initial evaluation and management. Hypovolemia may be relatively well tolerated in the young patient without underlying disease but can be a significant stress to elderly or chronically ill individuals whose compensatory mechanisms may be overwhelmed and whose tissue perfusion may be marginal at baseline (10,11).

Patients with anemia secondary to chronic blood loss or to decreased red cell production often present with signs and symptoms involving several systems due to hypoperfusion and decreased oxygen-carrying delivery:

- Constitutional symptoms—progressive fatigue, malaise, or dizziness
- Integumentary symptoms—pallor of the skin or mucous membranes, jaundice (from hemolysis), petechiae or purpura (with thrombocytopenia), or glossitis (from vitamin deficiency) (1,2,12)
- Pulmonary symptoms—dyspnea on exertion or decreased exercise tolerance
- Gastrointestinal symptoms—anorexia or nausea, hepatomegaly (from extramedullary hematopoiesis, sequestration or autoimmune process) (1,3,13)
- Cardiovascular symptoms—angina pectoris, claudication, syncope, tachycardia with widened pulse pressure, hyperdynamic precordium from increased cardiac output, or systolic ejection murmur (1,2,14,15)
- Genitourinary symptoms—dark urine (from hemolysis) or decreased urine output (16)
- Neurologic symptoms—focal neurologic deficits, stocking glove anesthesia or impaired position or vibratory sense (due to vitamin B_{12} deficiency) (6,12)

Other important historic information includes ethnicity and family history (predisposition to certain hemoglobinopathies and pernicious anemia), drug use, dietary history, use of ethanol, recent hospitalization (anemia of chronic disease is common in hospitalized patients), and history of underlying disease (renal,

hepatic, thyroid, collagen vascular, or neoplastic disease; previous anemia; or recurrent jaundice) (3,17). Chronic rheumatologic, endocrine, hepatic, or neoplastic disease may manifest with lymphadenopathy, rash, thyromegaly, myxedema, or the stigmata of liver failure (15,16).

The symptoms, signs, and laboratory findings of anemia may be the initial presenting manifestations of pancytopenia (1). The etiology of pancytopenia is multifactorial. Pancytopenia is most commonly idiopathic (50%) but may result from chemical and physical agents, autoimmunity, or vitamin B_{12} or folic acid deficiency. Pancytopenia may follow viral illness, including upper respiratory infection, hepatitis, Epstein–Barr infection, and human immunodeficiency virus infection (1,18). It may also be associated with hypersplenism, myelodysplasia, bone marrow failure, or marrow replacement (3). Clinically, pancytopenia may present as a viral illness, preceding the symptomatic presentation of anemia over several weeks, or as an insidious presentation of anemia with clinical evidence of thrombocytopenia (petechia, purpura, or mucous membrane bleeding) (1).

Patients with anemia secondary to acute hemolysis are likely to present with signs and symptoms similar to those seen with mild chronic anemia. In more severe presentations, there may be jaundice and dark urine. Fever, prostration, abdominal and back pain, and hemoglobinuria suggest acute intravascular hemolysis, similar to that associated with transfusion reaction (1,8). A family history of anemia suggests an intrinsic cause of hemolysis, whereas exposure to drugs or toxins suggests an extrinsic cause (1,3). Immunologic destruction of red blood cells may be due to autoantibodies (8). Mechanical destruction is seen in some patients with prosthetic heart valves (3). Disseminated intravascular coagulation leading to microangiopathic hemolytic anemia is suggested by diffuse bleeding (13,15).

DIFFERENTIAL DIAGNOSIS

A complete differential diagnosis is presented in Table 200.1.

ED EVALUATION

Patients presenting to the ED with hypovolemic shock due to acute blood loss need to be rapidly evaluated and stabilized. Cases of chronic anemia can be evaluated on a less emergent basis, and some patients may continue their evaluation as an outpatient. In-patient evaluation may include further laboratory evaluation for specific diseases as well as a bone marrow biopsy in some cases (3).

Potential diagnostic errors of importance include the following:

- Not suspecting acute blood loss and impending hypovolemic shock with any unexplained normocytic normochromic anemia
- Confusing anemia with other entities that also cause constitutional symptoms (e.g., uremia, collagen vascular disease, fluid and electrolyte imbalance, infections, drug effects)
- Confusing iron-deficiency anemia, which presents with low iron, increased total iron-binding capacity (TIBC), and low ferritin, with anemia of chronic disease, which presents with low iron, low TIBC, and normal ferritin associated with a chronic disease or recent hospitalization (1,3,10)
- Confusing hemolytic anemia with other entities that also cause acute jaundice (particularly acute hepatitis)
- Overlooking pancytopenia by focusing on a clinical picture of anemia and low hemoglobin while neglecting findings of leukopenia and thrombocytopenia

KEY TESTING

Initial testing in the ED should include the following:

- Complete blood count
- Red blood cell indices and reticulocyte count
- Peripheral smear (hemolyzed cells, basophilic stippling, ringed sideroblasts, or hypersegmented leukocytes may be seen) (1,4,7,16)
- Additional focused laboratory analysis for specific conditions
- Serum iron, TIBC, and serum ferritin for hypochromic microcytic anemia (3)

- Folate and vitamin B_{12} levels, liver-function tests, and thyroid-function tests for macrocytic anemia (3,12)
- Indirect Coombs tests, fractionated serum bilirubin count, and lactate dehydrogenase (LDH) and haptoglobin levels in hemolytic anemia (8,12,19)

ED MANAGEMENT

Anemia of pregnancy is treated with prenatal vitamins (one daily) and iron replacement (ferrous sulfate 325 mg three times per day), and hypochromic microcytic anemia associated with an identified source of blood loss (presumed to be due to iron-deficiency anemia) is treated similarly, with iron replacement therapy (5,10,20). These patients should be re-evaluated after 4 to 6 weeks to assess the adequacy of the therapeutic response (5,10).

In megaloblastic anemia, presumed to be due to folic acid or vitamin B_{12} deficiency, treatment may be initiated with 1 mg/d of oral folic acid or with vitamin B_{12} intramuscularly at a dose of 1 mg weekly for 8 weeks (6,10,12,17,18). High doses of oral vitamin B_{12} daily for 90 to 120 days (1 to 2 mg) have been shown to be as effective and safe as intramuscular administration (12). In mild or asymptomatic anemia of chronic disease, therapy is generally directed to control the underlying disease (3).

For severe or sympatomatic anemia, transfusion may be indicated, sometimes in the ED. There is still uncertainty regarding the "transfusion threshold" for critically ill or septic patients or patients experiencing a STEMI. Recent literature suggests that a threshold hemoglobin of 7 may be associated with better outcomes for critically ill adults and children and for patients with acute myocardial infarction (MI) (19,21,22).

In many cases of newly identified anemia, drug therapy and other interventions including the use of erythropoietin have been shown to be beneficial but are frequently not indicated in the ED setting, and patients are referred to a consultant for further evaluation and management (5,7,9,14,16,18,23).

In children, the most common causes of anemia are nutritional deficiencies or hereditary or acquired primary hematologic disorders (3). Treatment is directed toward the underlying cause (2).

CRITICAL INTERVENTIONS

- Recognize clinical signs and symptoms of anemia
- Initiate laboratory investigation for the underlying etiology of anemia

DISPOSITION

Consultation or referral for follow-up, in most cases, is to the patient's primary care physician. Most anemic adult patients have iron-deficiency anemia, vitamin B_{12}- or folic-acid–deficiency anemia, or anemia of pregnancy; these cases can be treated and followed up on an outpatient basis. Children who are symptomatic or severely anemic should receive a transfusion and be admitted to the hospital for further evaluation (2). Stable patients or those with mild anemia may be treated on an outpatient basis.

Urgent consultation and hospital admission should be sought for the following indications (3,10,17):

1. Hypovolemia or ongoing bleeding
2. Need for urgent transfusion, generally because of a hemoglobin level <7 g/dL in a bleeding or symptomatic patient (19,21), or to hemoglobin of 10 g/dL in septic patients in the first 6 hours or patients with acute MI (19,21)
3. Severe symptoms (e.g., chest pain, dyspnea, syncope) that impair the patient's ability to function at home
4. Pancytopenia requiring diagnostic evaluation (1,18)
5. Anticipated need for extensive diagnostic or therapeutic intervention

Unless active bleeding is present or the patient is hemodynamically unstable, there is usually no contraindication to routine transfer for specialized evaluation.

Common Pitfalls

- Failure to suspect and identify bleeding and hypovolemia.
- Failure to appreciate the possibility of anemia from the clinical presentation and, hence, not ordering a hemoglobin or hematocrit determination. This is especially likely in hemolytic anemia or when chest pain, dyspnea, dizziness, or claudication is the presenting complaint.
- Failure to identify and treat the underlying cause of the anemia.
- Failure to ensure referral or appropriate follow-up for evaluation of therapeutic response or the need for additional diagnostic testing.

ACKNOWLEDGMENT

The authors gratefully acknowledge the contributions of Louis S. Binder to the contents of this chapter.

CHAPTER 201

Transfusion Reactions and Complications

Gregory W. Hendey

Each year, approximately 24 million units of blood components are transfused to patients in the United States (1). The overall incidence of reported transfusion reactions is 0.25%, with only 0.09% being severe (1). The exceptionally low rate of serious transfusion reactions is mainly due to strict adherence to blood banking techniques, careful transfusion practices, and extensive testing of donated units.

Although life-threatening reactions are rare, it is critical that physicians recognize them quickly and respond appropriately to avert a disastrous outcome. Transfusion reactions may be divided by severity and time of onset (Table 201.1).

TABLE 201.1
Blood Transfusion Reactions and Complications

Acute, severe reactions
- Acute hemolysis
- Anaphylaxis
- Septic
- Transfusion-related acute lung injury
- Congestive heart failure

Acute, minor reactions
- Simple febrile
- Allergic

Delayed reactions
- Delayed hemolysis
- Graft-versus-host disease
- Hepatitis
- HIV
- CMV
- Other infections: Epstein–Barr virus, cytomegalovirus, syphilis, trypanosomiasis, babesiosis, malaria, toxoplasmosis, brucellosis, West Nile virus

Massive transfusion
- Coagulopathy
- Hypothermia
- Hypocalcemia (citrate toxicity)
- Hyperkalemia
- Lactic acidosis

CLINICAL PRESENTATION

Acute, Severe Reactions

Acute Hemolysis

One of the most serious (and most preventable) blood transfusion reactions is acute hemolysis caused by incompatibility between recipient and donor ABO blood groups. The incidence is approximately 1 in 600,000 components transfused (1). The resulting IgM–antigen complex fixes complement, leading to rapid intravascular hemolysis, with massive release of hemoglobin, acute renal failure, disseminated intravascular coagulopathy (DIC), and cardio-vascular collapse.

The most common cause is mislabeling or clerical error—the wrong unit is given to the wrong patient. For that reason,

painstaking efforts must be taken to double-check every step in the identification process prior to a transfusion.

The clinical signs of an acute hemolytic reaction are usually not subtle in patients who are awake but may be difficult to recognize quickly in unconscious, intubated patients. In an acute reaction, patients experience a rapid onset of fever, chills, back pain, vomiting, tachycardia, and hypotension.

Anaphylaxis

Anaphylaxis is fortunately a rare occurrence during a blood transfusion, but when it does occur, it is often in IgA-deficient individuals who react to the IgA present in the plasma of the transfused unit. The incidence has been estimated to be between 1 in 20,000 and 1 in 150,000 transfusions (2,3). Although these reactions are not predictable, they may be prevented in a patient with a history of anaphylaxis by minimizing plasma transfusions and transfusing products that are washed or derived from IgA-deficient donors (2).

The onset is generally within the first minutes of transfusion and presents as sudden flushing, pruritus, laryngospasm, bronchospasm, and hypotension.

Sepsis

Another potentially fatal transfusion reaction occurs when a contaminated blood product is transfused. This is a rare event with packed red blood cells (PRBC) transfusions, with only one reported fatality per year reported to the Food and Drug Administration (FDA) (4). The most common bacterium in PRBC units is *Yersinia enterocolitica,* which grows well under refrigerated conditions (4,5).

Platelet transfusions carry a higher risk of fatal sepsis due to bacterial contamination (approximately 1 in 700,000 units) because they are stored at room temperature to maintain platelet activity (1,4,5). Single-donor apheresis platelet units carry a slightly lower risk for bacterial contamination than do pooled random donor platelets as do fresher units with less storage time (4,5). Many bacteria have been implicated in platelet contamination, including *Staphylococcus aureus* and *Enterobacteriaceae.*

When the contaminated unit is transfused, it may produce the acute onset of a sepsis syndrome, with fever, chills, and hypotension. A septic reaction, especially when caused by a gram-negative organism, could easily be confused with the early stages of a hemolytic or anaphylactic reaction.

Transfusion-Related Acute Lung Injury

Transfusion-related acute lung injury (TRALI) is a noncardiogenic pulmonary edema occurring unpredictably in 1 in 50,000 units transfused (1,2,5). TRALI has emerged as the leading cause of transfusion-related fatality, with 91 cases reported to the FDA from 2007 to 2011, representing over 40% of reported fatalities (6). Antileukocyte antibodies in the donor unit (often fresh frozen plasma [FFP]) react with the patient's white blood cells, resulting in the release of cytokines. This reaction leads to increased pulmonary capillary permeability and produces an adult respiratory distress syndrome during or just after transfusion. It should be differentiated from acute congestive heart failure (CHF) by the patient's history and the typical chest x-ray (CXR) finding of diffuse interstitial edema without cardiomegaly. An association between TRALI and female plasma donors has been noted and is thought to reflect increased antibody production during pregnancy. For this reason, some blood banks now restrict plasma donations to males.

Congestive Heart Failure

The cardiovascular systems of most patients can easily accommodate the rapid change in intravascular volume that a blood transfusion provides. Elderly patients, however, and those with preexisting cardiomyopathy or diastolic dysfunction may have difficulty handling an acute change in volume and preload, and the result is pulmonary edema. Acute, progressive dyspnea and rales may develop during or soon after a blood transfusion, which some refer to as transfusion-associated circulatory overload (TACO).

Acute, Minor Reactions

Simple Febrile Reactions

Simple febrile reaction is the most common transfusion reaction, with an incidence of 0.1%. It is thought to be due to antileukocyte and antiplatelet antibodies or to transfused pyrogenic cytokines that accumulate in stored blood as leukocytes break down. It is characterized as an isolated fever during transfusion, without any of the more serious signs and symptoms of vomiting, back pain, hypotension, or evidence of hemolysis.

Allergic Reaction

Minor allergic reactions occur largely in response to transfused plasma proteins. The incidence is estimated to be 0.1%, but it may be underreported (2). The reaction is more common with platelet or plasma transfusions, but PRBC units also carry some residual plasma. The patient develops urticaria or flushing and pruritus, without the dyspnea or hypotension that may signify a more serious anaphylactic reaction.

Delayed Reactions

Adverse transfusion reactions may occur days to months after the transfusion. These include delayed hemolysis, graft-versus-host disease (GVHD), and a number of infections. Many infectious diseases may be transmitted by blood transfusion, including the human immunodeficiency virus (HIV), hepatitis, syphilis, malaria, cytomegalovirus (CMV), Epstein–Barr virus, trypanosomiasis, toxoplasmosis, babesiosis, brucellosis, and West Nile virus (1,7). The most clinically significant in the United States are hepatitis, HIV, and CMV.

Delayed Hemolysis

Delayed hemolysis is unusual but may occur 5 to 10 days after transfusion. The incidence is approximately 1 in 29,000 units transfused (1). It is most commonly caused by reactivation of antibodies to the minor RBC antigen systems such as Rh, Kell, Kidd, and Duffy. Clinically, it presents in a less severe and dramatic way than the acute hemolytic reaction in most cases (2). Low-grade hemolysis and progressively worsening anemia are the most common clinical findings of this reaction.

Graft-Versus-Host Disease

GVHD occurs when lymphocytes from a donated unit of blood attack an immunocompromised host who is unable to combat the foreign cells or when lymphocytes from an immunologically similar donor are not recognized as foreign by the host. Signs and symptoms may include fever, rash, nausea, and vomiting as well as elevation of transaminases and pancytopenia occurring 7 to 10 days after transfusion (2). This is a particular danger in neonates and bone marrow transplant recipients.

Hepatitis

Transfusion-associated hepatitis was a major problem in the 1970s and 1980s. It has been estimated that during the early 1970s, transfusion-associated hepatitis occurred in up to 33% of transfusions (8). Since then, aggressive screening of donors and the development of specific assays for hepatitis B (HBsAg and anti-HBc) and C (anti-HCV and nucleic acid amplification) have greatly reduced the risk.

Donahue et al. (9) reported a decrease in the risk of posttransfusion hepatitis C from approximately 1 in 200 during 1985 to 1 in 3,300 in 1991, after hepatitis C testing became available. With further advances in testing, the current estimated risk of transfusion-transmitted hepatitis B is 1 in 200,000, and that of hepatitis C is 1 in 2,000,000 (1,3,10).

Human Immunodeficiency Virus

Although it is now exceedingly rare, the transfusion complication that has received the most public attention is HIV infection. It has been estimated that the risk of HIV transmission in some metropolitan areas was as high as 1 in 100 units transfused in 1983 before HIV testing was available to blood banks in March 1985 (5). Now, thanks to aggressive predonation screening along with testing for HIV-1 and HIV-2 antibodies, p24 antigen testing, and nucleic acid amplification testing (NAT) technology for HIV, the current risk is estimated to be 1 in 2 million units of blood (1,10). NAT technology allows for the detection of viral genetic materials prior to the antibody response.

The use of concentrated pooled plasma products resulted in a majority of hemophiliacs in the 1980s contracting the acquired immunodeficiency syndrome or hepatitis. Highly purified, lyophilized factor VIII concentrate and recombinant products have eliminated these tragic complications of therapy.

Cytomegalovirus

Although CMV is generally not a significant pathogen in immunocompetent individuals, the immunosuppressed, especially premature neonates, HIV patients, and bone marrow and organ transplant recipients are especially susceptible to CMV infection transmitted by blood transfusion. The risk may be greatly reduced through the use of blood collected from CMV-negative donors or by using leukocyte-reduced or frozen-deglycerolized units of blood.

Massive Transfusion

Several alterations are present in stored blood that are insignificant in small transfusions but may become clinically relevant in the setting of massive transfusion. *Massive transfusion* is usually defined as transfusion of the equivalent of one blood volume, or 10 to 12 units of PRBC, within 24 hours (11). Although this situation is unusual in the emergency department (ED), it may be encountered in the setting of major trauma or gastrointestinal (GI) bleeding when definitive care is delayed for whatever reason. A more recent and relevant definition of massive transfusion may be the transfusion of 6 units of PRBC within 3 hours, with ongoing hemorrhage.

Hyperkalemia and lactic acidosis may result from the transfusion of multiple units of older stored blood, but the effects tend to be relatively mild and transient. Hypocalcemia due to citrate toxicity was a significant clinical issue in the past when it was common to transfuse whole-blood units. However, in the era of component therapy, whole blood is rarely available or indicated, and PRBC units contain far less citrate. Transfusing large amounts of cold blood may also cause hypothermia, which in turn may worsen coagulopathy. Blood warmers lessen this problem, but may also slow the rate of

transfusion. Mixing PRBC units with heated crystalloids, making the transfusion both faster and warmer, has been described (12,13).

The coagulopathy associated with massive transfusion is multifactorial. Dilutional effects play a part, as the multiple units of PRBC transfused contain only negligible amounts of clotting factors and platelets. Trauma patients who receive more than 10 units in 24 hours are more likely to develop serious coagulopathy, especially in the presence of hypothermia, acidosis, or hypotension (14). Although platelet counts fall during massive transfusion, the decrease is less than would be predicted from dilution alone (15). This may be due to an "auto-transfusion" effect from platelets stored in the spleen or bone marrow.

DIFFERENTIAL DIAGNOSIS

The patient who develops any adverse symptoms early in a blood transfusion must be carefully evaluated for the possibility of one of the acute, severe reactions. However, many patients who receive emergent transfusions have underlying disease that may have symptoms in common with transfusion reactions. For example, when trauma patients or those with GI bleeding become hypotensive during a transfusion, the hypotension may represent either increasing hemorrhage or an acute, severe transfusion reaction. Sepsis and some drug overdoses (i.e., salicylates) may also present with symptoms that are similar to those of a transfusion reaction. Hypotensive reactions to platelet transfusions have also been reported (16). These are not thought to be allergic in origin but may initially lead the clinician to suspect anaphylaxis. These reactions appear to be uncommon and resolve quickly with cessation of the platelet transfusion (16). Patients with fever may have infectious causes unrelated to the blood transfusion, and those with allergic symptoms may be reacting to an allergen other than a blood product.

Although many of the signs and symptoms of transfusion reactions are nonspecific and can be confused with many disease processes, most transfusion reactions occur during or soon after a transfusion. The temporal relationship is less clear with the delayed reactions. A delayed hemolytic reaction must be differentiated from other causes

of jaundice and anemia, but the indirect hyperbilirubinemia should cue the physician that hemolysis has occurred. A new diagnosis of hepatitis or other transmissible diseases may be traceable to the blood supply but may also have occurred independently.

ED EVALUATION

In the patient with an acute reaction, the clinician must immediately *stop the transfusion* and rapidly decide whether the signs and symptoms are consistent with one of the severe reactions or one of the more benign febrile or allergic reactions (Fig. 201.1). Differentiation may sometimes be done clinically by evaluating the constellation of findings, without extensive testing. One may also employ quick, simple testing, such as observing the serum (after centrifugation of a blood sample) or the urine for pink discoloration during a hemolytic reaction.

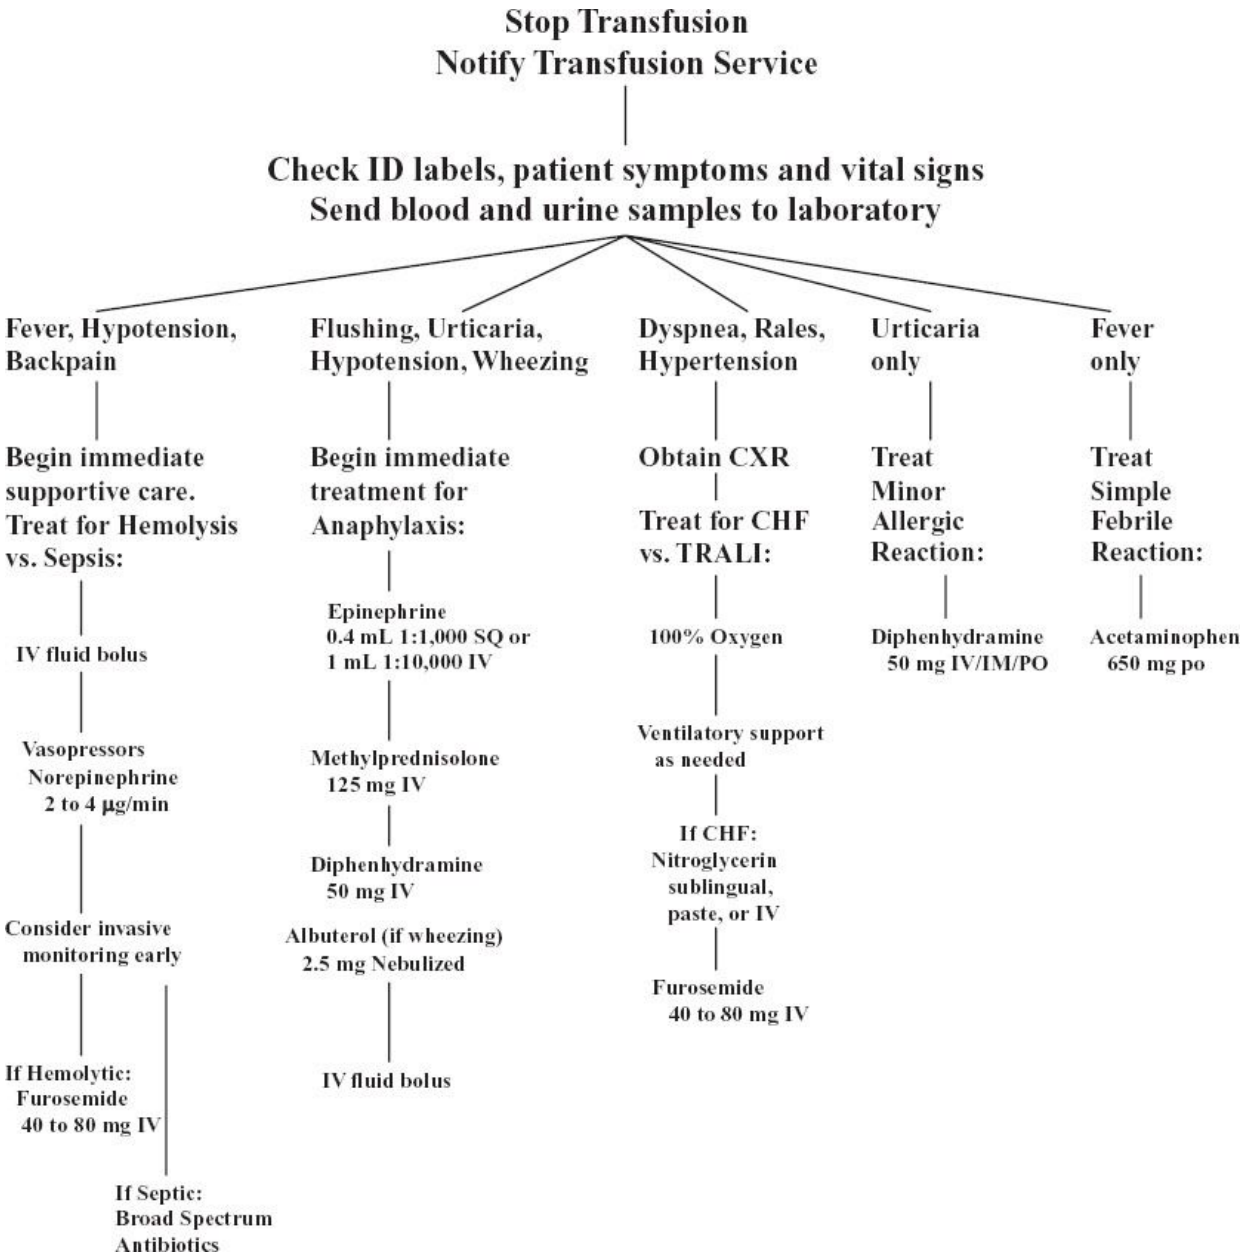

FIGURE 201.1 Clinical algorithm for suspected transfusion reaction. Many hospitals have developed policies and guidelines for actions to be taken in case of a transfusion reaction. Physicians should be informed regarding local hospital policy. TRALI, transfusion-related acute lung injury.

The evaluation should also involve immediate reporting to the laboratory and sending blood samples for testing. Based on the clinical setting, the laboratory will often confirm the ABO types of

the patient and donor unit, perform a direct Coombs test, and search for evidence of hemolysis (an elevated indirect bilirubin, decreased haptoglobin, schistocytes on a peripheral smear, or hemoglobinuria). Testing may also include Gram staining and cultures, especially after platelet transfusions, if bacterial contamination is suggested.

The transfusion must be stopped during this critical evaluation period until the clinician is certain that a severe reaction has been excluded. In many cases of minor reactions, the clinician may choose to treat the symptoms and restart the transfusion, although this remains controversial and varies by institutional policy. One should quickly involve the laboratory and transfusion service for consultation when a reaction occurs. Most institutions have policies or guidelines to help the clinician in evaluating and reporting transfusion reactions.

KEY TESTING

- Send samples of patient's blood and transfusion component to lab
- Type and screen, direct Coombs test, hemoglobin, urinalysis, bilirubin, haptoglobin, peripheral smear

ED MANAGEMENT

Treatment depends on which type of reaction has occurred (see Fig. 201.1). The first step is always to stop the transfusion and carefully evaluate the patient to determine whether a transfusion reaction is occurring and, if so, which type.

The treatment of *acute hemolysis* is largely supportive, with special attention to maintaining renal perfusion. In hemodynamically unstable patients, early use of invasive monitoring is warranted, along with vasopressors and forced diuresis with crystalloids and loop diuretics (e.g., furosemide). Other treatments, such as steroids, mannitol, or heparin for DIC, are more controversial.

Anaphylaxis should be treated with epinephrine, steroids, diphenhydramine, and IV fluids. Patients with a history of serious allergic reactions to blood products may be given washed RBCs or frozen-deglycerolized RBCs in an effort to prevent allergic reactions.

IgA-deficient donors are often available when the transfusion can be planned in advance.

Sepsis from bacterial contamination requires aggressive supportive care, including IV fluids, vasopressors, and broad-spectrum antibiotics. Antibiotic coverage for a contaminated platelet transfusion should include an antistaphylococcal agent as well as a third-generation cephalosporin. Coverage for a contaminated PRBC transfusion must include a third-generation cephalosporin or quinolone to cover *Yersinia.*

CHF is treated with nitrates, diuresis, and ventilatory support as needed. Transfusions must be given carefully in elderly patients and in those with a history of CHF or renal failure. It may be sufficient to transfuse each unit slowly (over 3 to 4 hours) and allow a period of time between subsequent units transfused, usually in the inpatient setting. Administration of a loop diuretic (e.g., furosemide) between units may also be helpful. In high-risk patients, invasive monitoring of right or left ventricular filling pressures in the ICU may be necessary, and transfusions may be accomplished during dialysis for renal failure patients.

TRALI, or noncardiogenic pulmonary edema, has no specific treatment and may require supplemental oxygen, continuous positive airway pressure (CPAP or BiPAP), or intubation and ventilatory support. In many cases, the pulmonary edema resolves spontaneously over hours to days. Limiting plasma donors to males might reduce the incidence of TRALI.

Simple febrile and *allergic* reactions are treated with acetaminophen and diphenhydramine, respectively, but must be differentiated from the more dangerous transfusion reactions. Patients who receive frequent transfusions or who have a history of minor reactions may be given leukocyte-reduced units to reduce the risk of a febrile reaction or pretreatment with diphenhydramine to reduce allergic symptoms. There is controversy about whether the transfusion may be carefully resumed after clinical observation and appropriate laboratory testing have ruled out a more serious reaction.

For GVHD, there is no specific treatment beyond supportive care, but some preventive measures exist. Irradiation of PRBC and platelet

units suppresses white blood cells that may be transfused along with the desired component and may prevent GVHD in high-risk immunocompromised patients.

The many problems associated with *massive transfusion* may be dealt with in several ways. Prevention of hypothermia and monitoring for hyperkalemia and hypocalcemia are important. In cases of massive transfusion over many hours or days, coagulopathy may be monitored with serial laboratory testing. When massive transfusion occurs more quickly, a formulaic approach to the prophylactic administration of FFP and platelets is appropriate. For example, 10 units PRBC → transfuse 4 units FFP and 1 apheresis platelet unit. Many authors now recommend early, aggressive replacement of FFP and platelets during massive transfusion (17).

CRITICAL INTERVENTIONS

- With any sign of a transfusion reaction, stop transfusion immediately and closely monitor vital signs.
- Administer IV fluid bolus if hypotension is present.
- Send samples from patient and transfusion unit to lab.

DISPOSITION

Most patients receiving blood transfusions in the ED are ultimately admitted to the hospital, regardless of whether they have a transfusion reaction. However, acute, severe reactions usually necessitate ICU admission, regardless of the patient's original disposition. Simple febrile or allergic reactions do not necessarily require a change in the patient's treatment plan.

Common Pitfalls

- Failure to carefully identify patients when drawing pretransfusion blood samples and to carefully match identities of blood components, their paperwork, and the recipient. This is the most frequent cause of fatal hemolytic reactions.
- Failure to adequately evaluate a patient who develops symptoms during a blood transfusion. The large majority of reactions are

simple febrile or allergic reactions, but the few dangerous reactions must be recognized and treated immediately.

- Failure to recognize a severe reaction in an intubated patient. Because the patient cannot complain of symptoms, it is more difficult to differentiate a transfusion reaction from underlying disease. An acute, severe reaction may initially appear as isolated hypotension, fever, or hematuria.
- Rapidly transfusing an elderly patient who is inadequately observed. CHF can be avoided by slow, intermittent transfusion and diuresis.

CHAPTER 202

The Cancer Patient in the Emergency Department

Gwendolyn M. Schillo and Joanne Williams

Cancer is the second leading cause of death in the United States. In fact, one in every four deaths in the United States is a result of cancer or related illnesses. A new diagnosis of cancer may occur during an emergency department (ED) visit, but a more common scenario is one wherein the emergency physician treats an individual with a history of malignancy who suffers a complication of the disease or its treatment.

ED visits for cancer and related complications have increased, not only as a result of disease prevalence, but from changes in treatment. More aggressive chemotherapy regimens have improved patient survival and cure rates but have also resulted in an increased number of complications related to therapy. Common oncologic emergencies facing the emergency physician include metabolic abnormalities (e.g., hypercalcemia and tumor lysis syndrome [TLS]), superior vena cava syndrome, malignant pleural effusion, and neutropenic fever. The emergency physician must be prepared to assess and begin lifesaving treatments for these conditions.

SHORTNESS OF BREATH

Airway Obstruction

The first priority in assessing the patient with shortness of breath is to assess the airway, seeking evidence of obstruction. Most cases of upper airway obstruction involve advanced cases of cancers of the

larynx or the hypopharynx, neck, and mediastinum. Patients with head and neck malignancies will typically present with a history of gradual dyspnea progressing over the course of weeks to months. Additional symptoms may include hoarseness or stridor, dysphagia, and hemoptysis.

Tumors, most commonly carcinoma of the lung, esophagus, thyroid, and lymphoma, cause dyspnea by direct invasion or compression and mass effect of the trachea. Midline shift of the trachea may be apparent on physical examination or radiograph. Obtaining an emergent and definitive airway on these patients may be difficult, as tumors can block the view of the vocal cords or can be subglottic in location, making passage of an endotracheal tube impossible. Tracheostomy is often necessary, as endotracheal intubation can be unsuccessful.

Bronchial obstruction is usually the result of primary lung carcinoma. Rarely, endobronchial metastasis from other primaries such as breast, colon, and renal carcinoma cause significant bronchial obstruction. Typically, there must be more than 75% obstruction before a patient becomes symptomatic. The patient may present with dyspnea on exertion, cough, hemoptysis, wheezing, and rhonchi.

Initial assessment may include x-rays of the chest and soft tissues of the neck. Unfortunately, these are rarely diagnostic; thus, contrast computed tomography (CT) scan with contrast of the neck and chest with three-dimensional airway reconstruction is more helpful. Direct laryngoscopy or nasopharyngeal approaches with fiberoptic scopes are often used to assess the size of the airway lumen and involvement of the vocal cords when upper airway obstruction is suspected. Unfortunately, tumors causing acute airway compromise from edema, infection, hemorrhage, or excessive secretions do not allow time for imaging and determination of anatomic changes. In such situations, one must be prepared to establish an emergent surgical airway. Early involvement of an ear, nose, and throat surgeon is recommended, as the local anatomy of the airway can be greatly distorted. This is particularly true if the patient has been treated previously with tumor resection or radiotherapy or if the

patient has untreated bulky masses. Interventions prior to intubation could include high-flow supplemental oxygen or bag-valve-mask ventilation, heliox, intravenous steroids, racemic epinephrine, and antibiotics.

Pneumonia

When patients present with dyspnea, fever, and sputum production, pneumonia should be suspected. Patients with pulmonary obstructing lesions such as primary lung cancer, lymphomas, or metastasis to the lung are more prone to pneumonia. Other populations at increased risk for pneumonia are those with a history of head and neck cancer, with or without previous surgical treatment, with secondary aspiration, and those with hematologic malignancies or neutropenia who are on chemotherapeutic drugs. Diagnosis is made easily by chest x-ray or CT, and appropriate antibiotic therapy should be started promptly. Patients with postobstructive pneumonia may require bronchial stenting or radiotherapy to definitively treat the pneumonia.

Malignant Pleural Effusion

Malignant pleural effusions are caused most commonly by lymphoma, lung, or breast cancer and less commonly from ovarian and gastrointestinal cancers. Malignant effusions arise from various mechanisms, including tumor emboli seeding the visceral and parietal pleural surfaces, direct tumor invasion, and lymphatic obstruction. Local inflammatory changes in response to tumor invasion may also result in effusion. Rarely, an effusion can be due to congestive heart failure resulting from cardiomyopathy caused by certain chemotherapeutic agents.

It is estimated that up to 30% of cancer patients develop malignant pleural effusion. Patients typically present with dyspnea on exertion or orthopnea or may complain of a dry cough. Examination typically reveals decreased breath sounds on the affected side, dullness to percussion, and occasionally a pleural friction rub.

Chest x-ray or CT confirms the diagnosis. Approximately 300 cm^3 of fluid is needed for an effusion to be seen on an upright chest x-ray and only 100 cm^3 on a decubitus film. For a small effusion with mild hypoxemia, only supplemental oxygen may be needed. Thoracentesis may be required for intractable hypoxemia due to moderate or massive effusion. Pleural fluid obtained during thoracentesis should be sent for cytology, gram stain, culture, cell count and differential, protein, amylase, and lactate dehydrogenase (LDH) determinations. If infection is suspected, antibiotics should be started after a sample of pleural fluid is obtained. For recurrent effusions, an oncologist should be consulted for more definitive therapeutic modalities such as pleurodesis, pleurectomy, or chemotherapy.

Pericardial Effusion

Pericardial effusion occurs most commonly in patients with lung and breast cancer, but virtually any tumor can involve the pericardium. Pericardial effusions leading to tamponade are usually the result of long-standing processes that evolve into critical problems over the course of a few hours. The severity of tamponade is related to the rapidity with which fluid accumulates (see Chapter 88). Slowly increasing effusions allow time for the pericardium to stretch and slowly accommodate the increased volume. If the pericardium is thickened by fibrosis and therefore less compliant, as is often the case in patients who have received radiotherapy to the mediastinum, even a small effusion can cause tamponade. In such cases, chest radiograph may show a small heart, and cardiac tamponade can be confirmed only by the use of a bedside echocardiogram.

Nonconstricting pericardial effusion usually does not cause specific symptoms. However, as the pericardium distends and compression worsens, patients may develop dyspnea, orthopnea, chest pain relieved by leaning forward, cyanosis, dysphagia, hoarseness, epigastric discomfort, or hiccups. On physical examination, the patient is typically apprehensive and diaphoretic,

with a decreased systolic blood pressure and a narrowed pulse pressure. The lungs are usually clear, the neck veins distended, and the heart sounds distant. An increased pulsus paradoxus and inspiratory swelling of the neck veins may be noted. If the effusion is a long-standing one, patients may also have peripheral edema, hepatojugular reflux, hepatomegaly, and even ascites, giving the impression that congestive heart failure is present.

The chest x-ray shows cardiomegaly or a globular cardiac silhouette with clear lung fields. The most common electrocardiogram (ECG) findings are sinus tachycardia and low-voltage QRS complexes or occasionally global ST elevation. Electrical alternans is pathognomonic for pericardial effusion but is commonly missed as it can disappear as compression worsens. Definitive diagnosis is made by echocardiography or CT when ultrasound is unavailable. Bedside ultrasonography may also be used to guide pericardiocentesis in the decompensated tamponade patient. Treatment of frank tamponade also includes the administration of intravenous fluids to increase the right ventricular filling pressure. This alone may provide time to get the patient to surgery for a pericardial window procedure. If emergent pericardiocentesis is performed for shock, cyanosis, or decreased level of consciousness, the fluid should be sent for cytology.

Pulmonary Embolism

Patients with malignancy are in a hypercoaguable state and therefore are at risk of thromboembolic disease such as pulmonary embolism. Venous thrombosis can also form from external compression or direct invasion of vascular structures by tumors. Approximately 10% of all patients with cancer develop thromboembolic disease, and for patients with certain malignancies such as pancreatic, renal cell, and ovarian carcinomas, the incidence can be as high as 50%. As such, pulmonary embolism must always be considered a potential cause of dyspnea in cancer patients. Likewise, patients not known to have malignancy who are

diagnosed with thromboembolic disease, specifically those with recurrent thrombosis, should be screened for malignancy.

Treatment options include anticoagulation with heparin or, when there is a concern for heparin allergy or heparin-induced thrombocytopenia, with nonheparin-based anticoagulants such as direct thrombin inhibitors. The nonheparin-based anticoagulants should be administered in consultation with hematology. When starting anticoagulation in an oncology patient, particular attention should be given to the extent of metastatic disease, especially the presence of brain metastasis. Current opinion supports anticoagulation in the presence of brain metastasis, except possibly in cases of renal cell carcinoma or melanoma, which are more likely to develop hemorrhagic complications. For patients who cannot be treated with anticoagulants, an available option is placement of an inferior vena cava (IVC) filter. The risks of IVC filter placement include complications related to the insertion process, venous thrombosis at the site of insertion, filter migration or erosion into the IVC wall, and IVC obstruction. The risks of placement should be considered prior to insertion.

Superior Vena Cava Syndrome

Superior vena cava (SVC) syndrome is a result of the acute or insidious obstruction of blood flow in the SVC, resulting in elevated venous pressure or venous hypertension. The severity of illness is related to the rapidity of obstruction; the more rapid the onset of obstruction, the shorter the time available for development of collateral circulation. Structures drained by the SVC include the lower airways, upper extremities, neck, face, eyes, and brain. SVC obstruction therefore leads to dyspnea and hoarseness from edema of the airways, dysphagia, chest fullness, blurred vision, and headache. Common physical findings include venous distension of the neck and facial and upper extremity rubor and swelling. The patient's symptoms can usually be exacerbated by a change in position, such as bending forward, stooping, or lying down. As

venous hypertension increases, increased intracranial pressure (ICP) can develop and can lead to syncope.

Obstruction from malignancy is the most common etiology of SVC syndrome, accounting for up to 85% to 95% of cases. Patients have evidence of a mass on chest radiograph only 10% of the time. Chest CT is more sensitive for diagnosing a mass that is causing compression. When a mass is found, it is usually located in the right superior mediastinum. Other causes of SVC syndrome include mediastinal fibrosis from prior radiotherapy, tuberculosis, or thrombosis around indwelling venous catheters. Elevation of the head of the bed, diuretics, and steroids may reduce venous pressure and provide some temporary relief of symptoms. Definitive treatment, however, may include radiotherapy, antineoplastic agents, or percutaneous transluminal stent placement. Emergent radiotherapy is indicated when there is compromised cardiac function, significant upper airway edema leading to respiratory dysfunction, or cerebral dysfunction secondary to brain edema.

MASSIVE HEMOPTYSIS

Massive hemoptysis represents one of the most challenging conditions in clinical practice and this condition is potentially lethal. Patients die from asphyxiation or exsanguination.

Clinically, airway bleeding leading to life-threatening anemia, aspiration, airway obstruction, or hypovolemic shock is considered massive hemoptysis.

The most common cause of massive hemoptysis in cancer patients is bronchogenic carcinoma. Melanoma, breast, kidney, laryngeal, and colon cancers may cause hemoptysis secondary to lung metastases. Esophageal cancers may cause massive hemoptysis by direct extension into the tracheobronchial tree.

Patients with massive hemoptysis may present with hypotension, tachycardia, cold and clammy skin, dyspnea, cough, chest pain, or frank respiratory distress. These patients are true oncologic emergencies. Asphyxiation is the most frequent complication of massive hemoptysis. In that regard, these patients need

endotracheal intubation with the largest possible endotracheal tube, preferably 8-mm catheter or larger to facilitate bronchoscopy. Hypovolemic shock should be treated emergently. Once the airway is secure, the site of bleeding must be identified. A chest x-ray may show which side of the lung is bleeding. If bleeding site is known, place the patient in the lateral decubitus position with the affected lung in the dependent position which may be helpful to prevent aspiration to the unaffected side.

In unstable patients, unilateral intubation by way of a bronchoscope should be performed. The left mainstem bronchus is intubated over the bronchoscope for massive right-sided hemoptysis. The risk of right upper lobe occlusion is to be avoided. Therefore, unilateral intubation of the right lung with massive left-sided bleeding is not recommended. Another option is the utilization of a double lumen endotracheal tube introduced over the bronchoscope isolating the unaffected lung. Further treatment should be deferred to pulmonary or thoracic surgery specialists while resuscitation in the ED continues.

HEADACHES, SEIZURES, AND ALTERED SENSORIUM

Brain Metastasis

Melanoma and lung, breast, colon, and rectal cancers are the most common tumors that spread to the brain. Forty percent to 50% of patients with brain metastasis complain of headache. The headache is typically worse on awakening and improves during the course of the day. As 80% of metastases are located in the cerebrum, patients may additionally present with a history of progressive lethargy, memory loss, cognitive dysfunction, aphasia, paresis, or sensory disturbance. Cerebellar metastases, which account for $<10\%$ of metastases, usually cause dysmetria or gait disturbance. Papilledema is seen in $<10\%$ of patients, and a new seizure may be the first presenting complaint in about 15%. Of patients found to have brain metastasis without a known primary, 60% will be found to have pulmonary malignancy, either primary or metastatic. Diagnosis of

brain metastasis can be made with CT scan, ideally with contrast, or magnetic resonance imaging (MRI).

A cooperative effort between neurosurgery and medical and radiation oncology is needed to manage patients with both primary and metastatic brain tumors. However, immediate treatment is often needed in the ED to alleviate symptoms and reduce ICP. Corticosteroids reduce headache and improve function in 60% to 75% of patients with brain metastasis. Dexamethasone, the steroid of choice because of its high central nervous system (CNS) penetration, should be given as a 10 mg IV loading dose followed by 4 mg four times a day. Additionally, when there are physical or radiographic signs of increased ICP, the following interventions should be initiated: head of bed elevated to at least 30 degrees, fluid restriction, and administration of mannitol IV, 0.75 to 1 g/kg bolus followed by 0.25 to 0.5 g/kg every 3 to 5 hours. Consideration should also be given to radiotherapy and surgical decompression. Diuretics and hyperventilation are also effective short-term measures to reduce ICP.

When a patient has had a seizure, anticonvulsant therapy should be started promptly to prevent further seizure activity. Patients who present with seizures due to a brain tumor should be treated with a first-line anticonvulsant such as phenytoin, carbamazepine, or valproic acid. The agents should be given at the lowest effective dose. Additionally, in patients who are currently undergoing chemotherapy, levetiracetam, lamotrigine, or topiramate should be considered to avoid potential drug interactions, as these agents do not induce hepatic cytochrome P450 enzymes. The decision to administer anticonvulsants to patients with brain metastasis who have not had a seizure should be left to the oncologist or neurosurgeon. However, all patients with brain metastasis have the potential to have a seizure and so should be warned against driving or operating machinery.

Meningitis

When patients with a predisposing cancer present with headache, lethargy, or other vague CNS symptoms, meningitis, including carcinomatous meningitis, should be considered. After obtaining a CT scan to ascertain that there are no brain masses, a spinal tap should be performed. An opening pressure >16 cm H_2O, cerebrospinal fluid (CSF) leukocytosis, increased CSF protein concentration, and decreased CSF glucose concentration should raise suspicions about the presence of meningitis. An additional tube of CSF should be obtained for cytology.

Cancer patients with impaired cellular immunity, like patients with leukemia, lymphoma, or recent steroid use, can also have meningitis caused by atypical pathogens such as *Cryptococcus neoformans* or *Listeria monocytogenes.* Listeria is treated with ampicillin, as the organism is resistant to third-generation cephalosporins and Cryptococcus with amphotericin B. Encephalitis due to herpes simplex virus or varicella zoster virus should also be considered in this population when patients present with headache, low-grade fever, or bizarre behavior. Intravenous acyclovir is used for treatment of these infections. Patients with other bacterial infections such as sinusitis, otitis, or dental abscesses are at risk for contiguous CNS infections, including brain abscess.

Carcinomatous meningitis, or leptomeningeal metastasis, represents a malignancy that has arisen outside of the CNS and has seeded the dura, arachnoid, or pia mater of the brain or spinal cord. It is seen most commonly as a complication of breast and lung cancers, leukemia, and lymphoma. The symptoms of carcinomatous meningitis usually develop gradually and can be general or focal. There may be spinal cord involvement, with pain, headache, and radicular symptoms. Approximately 40% of patients with carcinomatous meningitis show evidence of cranial nerve dysfunction, such as diplopia or facial numbness referred to as “numb chin syndrome.” Evaluation includes CT or MRI to ascertain that there are no brain masses, followed by spinal tap. The classic CSF findings of carcinomatous meningitis include a high opening pressure (>16 cm H_2O), low glucose and high protein

concentrations, lymphocytic pleocytosis, and positive cytology for malignant cells. Although most patients do not have all of these features, an entirely normal CSF examination is uncommon. Treatment should be guided by neurosurgery and oncology consultants.

METABOLIC DISTURBANCES

Hypercalcemia

Hypercalcemia is relatively common in patients with cancer, occurring in about 20% to 30% of cases (see Chapter 212). The most common cancers associated with hypercalcemia include breast, lung and prostate cancers with bony metastasis, multiple myeloma, renal cell carcinoma, and lymphoma. The mechanisms for development of hypercalcemia include local matrix destruction by metastasis via cytokine release, tumor secretion of parathyroid hormone–like peptide, and tumor-mediated calcitriol secretion. Hypercalcemia of malignancy carries a poor prognosis, as the 30-day mortality is approximately 50%.

The severity of symptoms depends on the acuity with which one develops hypercalcemia. Although serum calcium levels may be as high as 15 mg/dL, symptoms of chronic hypercalcemia may be vague and include anorexia, nausea and vomiting, constipation, fatigue, and memory loss. An acute rise in the serum calcium level causes marked CNS effects including lethargy, somnolence, and even coma. When hypercalcemia is acute, severe symptoms may be seen at lower serum levels than chronic hypercalcemia. In general, serum levels of calcium >13 mg/dL are considered medical emergencies and should be treated as such. Assessment of hypercalcemia in the ED includes evaluation of other electrolytes and renal function and an ECG. ECG changes seen with hypercalcemia include a shortened QT interval.

Treatment of hypercalcemia depends on the calcium level and the patient's clinical status. Serum levels below 13 mg/dL, with mild symptoms, may be treated with oral or IV hydration alone. Patients with higher serum concentrations or more profound symptoms

should be treated with IV fluids, loop diuretics, and bisphosphonates. Patients are generally volume-depleted because of poor oral intake and depressed mental status and require aggressive hydration to achieve euvolemia or mild hypervolemia and are then given diuretics. Loop diuretics such as furosemide increase calcium excretion, whereas thiazide diuretics increase reabsorption and should be avoided. Pamidronate, a bisphosphonate, works by inhibiting bone resorption and is given as a continuous infusion of 90 mg over 4 hours. Additional treatments can include glucocorticoids, mithramycin, calcitonin, and dialysis. Patients should be admitted to a telemetry or intensive care unit bed, and potassium, magnesium, and phosphorus levels should be checked every 4 to 6 hours and repeated as needed.

Hyponatremia

Hyponatremia is another metabolic disturbance that can cause depressed mental status in cancer patients and is usually a result of the ectopic secretion of an antidiuretic hormone or syndrome of inappropriate antidiuretic hormone (SIADH) (see Chapter 210). It most commonly occurs with lung (especially small-cell), pancreatic, and ovarian cancer, lymphoma, thymoma, and brain tumors. SIADH causes hyponatremia by interfering with urinary dilution and thus preventing the excretion of ingested water. Patients with hyponatremia often do not have symptoms unless there is an acute drop in the sodium level or the serum sodium falls below 120 mEq/dL. Symptoms can include muscle twitching, seizures, and coma. The initial treatment of SIADH in the ED always includes fluid restriction.

In the emergency setting, correcting hyponatremia too rapidly may result in central pontine myelinolysis (CPM) with permanent neurologic deficits. In that regard, aggressive treatment of hyponatremia should always be weighed against the risk of inducing CMP. Patients who are actively seizing owing to hyponatremia should receive hypertonic saline solution (3% saline), which should be administered at 25 to 100 mL per hour until the seizure stops.

Additionally, furosemide can be given to reduce total body fluid volume. In cases of chronic hyponatremia, correction of the serum sodium should proceed slowly, at rates no faster than 10 to 12 mEq/dL/d. Use of hypertonic and isotonic solutions to rapidly increase the serum sodium levels in patients with long-standing hyponatremia can result in osmotic demyelination or central pontine myelinolysis.

Hypernatremia

An altered sensorium can also be the result of hypernatremia in cancer patients (see Chapter 210). Causes include reduced water intake or excessive gastrointestinal fluid loss related to chemotherapy. Generally, in cases of acute hypernatremia, sodium correction can be achieved rapidly without problems, but if the patient is chronically hypernatremic, correction should be gradual, especially in children. Patients with a history of congestive heart failure should be monitored for volume overload. Diuretics may be required in this patient population.

Tumor Lysis Syndrome

Tumor lysis syndrome (TLS) is most commonly associated with hematologic malignancies and solid tumors with a high rate of cell turnover or rapid tumor necrosis. The release of intracellular products (e.g., uric acid, phosphates, calcium, potassium) overwhelms the body's homeostasis mechanisms. The disorder can result in fatigue and altered mental status as a result of multiple homeostatic derangements including acidosis, acute renal failure due to urate nephropathy, hyperphosphatemia, hypocalcemia, and hyperkalemia. TLS typically presents within 1 to 5 days after irradiation or chemotherapy but can occur independent of treatment regimen. The incidence is significantly reduced by pretreatment with allopurinol and fluids before chemotherapy or radiotherapy.

The diagnosis should be suspected in patients with a large tumor burden who develop acute renal failure in the presence of marked hyperuricemia (>15 mg/dL) and hyperphosphatemia (>8 mg/dL).

Treatment in the ED includes IV hydration, administration of allopurinol or uricase, and urinary alkalinization. Hemodialysis should be used in patients in whom diuresis cannot be induced and volume overload is a concern. Hyperkalemia is the most dangerous component of TLS because it can cause sudden death due to cardiac dysrhythmias and should be addressed emergently with the standard treatment for hyperkalemia.

MUSCULOSKELETAL COMPLAINTS

Spinal Cord Compression

Any vertebral pain in patients with a history of cancer should alert the emergency physician to the possibility of vertebral or epidural metastasis and the potential for spinal cord compression (SCC). The incidence of SCC in cancer patients is estimated at 5% to 10%, regardless of tumor type. Metastatic tumor from any primary site can produce cord compression, but the most common are metastases from prostate, breast, or lung, and renal cell carcinoma; non-Hodgkin lymphoma; and multiple myeloma. Sixty percent of cases occur in the thoracic spine, 30% in the lumbosacral spine, and 10% in the cervical spine. Approximately 20% of cord compressions are the first manifestations of malignancy.

Pain is the initial symptom of SCC in 80% to 95% of patients and may have been present for several weeks to months prior to onset of neurologic symptoms. On average, pain precedes other neurologic symptoms by 7 to 8 weeks. It is usually exacerbated by lying flat, sneezing, coughing, or bearing weight, and abrupt worsening may herald a pathologic compression fracture.

Neurologic findings vary with the location of the tumor and the degree and duration of cord impingement. Motor findings are present in 60% to 85% of patients at the time of diagnosis. As they may be subtle, a thorough examination should be performed, including assessment of gait and the ability to walk on heels and toes. About half of patients present with sensory findings. Bladder and bowel dysfunction is a late finding of SCC.

Patients with cancer and even those with a remote history of a malignancy that has been associated with SCC that present with back pain or new-onset back pain should be evaluated for SCC as soon as possible. Plain radiographs provide information about bony destruction, collapse, and calcification but do not provide adequate information about the spinal cord. MRI, with a sensitivity of 93%, a specificity of 97%, and an overall accuracy of 95% remains the gold standard to evaluate the vertebrae, spinal cord, and epidural space. If MRI cannot be performed, CT myelography provides another option. ED treatment includes pain control and corticosteroids. Patients with neurologic findings should receive a bolus of 10 mg of dexamethasone, followed by 4 mg every 6 hours. Cord compression may also be treated with radiotherapy or tumor debulking, and thus prompt neurosurgical and radiation oncology consultation should be obtained when SCC is suspected.

Bony Metastasis

The sudden onset of pain in the cancer patient, commonly in the extremities, pelvis, or spine, may be due to pathologic fracture. At particular risk are patients with prostate, breast, or lung cancer and those with multiple myeloma. Minor trauma, an unusual mechanism of injury, or a transverse fracture line should heighten suspicion for a pathologic fracture. Recent negative bone scans can often be misleading, especially in patients with cancers such as myeloma and some prostate cancers that may produce purely lytic lesions. Plain radiographs establish the diagnosis, and emergent orthopedic consultation is required for immediate care as well as follow-up. Adequate analgesia must be provided to these patients.

COMPLICATIONS OF CANCER THERAPY

Neutropenia with Fever

Neutropenia is a common oncologic emergency. It may represent natural disease progression in patients with hematologic malignancies or with advanced disease in patients with metastatic solid tumors. Much more commonly, however, neutropenia develops

as a result of myelosuppression from cancer chemotherapy. Neutropenia is defined as absolute neutrophil count (ANC) <500 cells/μL or as a count $<1{,}000$ cells/μL and a predicted nadir of <500 cells/μL. The ANC is the total number of white blood cells (WBCs) multiplied by the percentage of neutrophils plus bands. As the total number of neutrophils decrease, the incidence of occult infection increases; the highest incidence of infection is in patients with an ANC <100 cell/μL. The nadir in ANC occurs 5 to 10 days after the last dose of outpatient chemotherapy. In the case of inpatient therapy, most notably those used in the treatment of hematologic malignancies, the decline in the ANC tends to be of greater depth and duration.

Fever in the cancer patient can be a result of transfusions, antineoplastic drugs, tumor necrosis and, more commonly, infection. Fever, defined as a single temperature >38.3°C or a temperature of at least 38°C for more than 1 hour, is a medical emergency in the neutropenic patient. Fever should be presumed to have an infectious etiology in these individuals, and they should be started on antimicrobials immediately. The 48-hour mortality associated with untreated infection in the neutropenic patient can be as high as 20% to 50%. Historically, infections were due predominantly to gram-negative bacilli, particularly *Pseudomonas aeruginosa.* However, with the use of indwelling catheters there has been an increase in gram-positive infections. Other factors increasing the risk of infection in the cancer patient include poor nutritional status, debilitation from recurrent hospitalization, and skin and mucous membrane disruption from chemotherapy, radiation, or tumor invasion.

Neutropenic patients may have only subtle signs of infection or may present only with hypothermia or hypotension. Thus, a thorough examination should be performed. Careful attention should be paid to the skin, indwelling catheters, and the perianal area. Laboratory evaluation includes a complete blood count (CBC), electrolytes, urinalysis, blood urea nitrogen, Cr, urine culture, chest x-ray, and at least two sets of blood cultures, including samples from any indwelling catheters.

Treatment regimens include initial empiric antibiotic therapy with two antibiotics (an extended spectrum beta-lactam with antipseudomonal activity, such as piperacillin or ceftazidime, plus an aminoglycoside). Monotherapy is also frequently used and may consist of ceftazidime, meropenem, imipenem, cefepime, or piperacillin–tazobactam. Vancomycin should be added for patients with catheter site infection, methicillin-resistant *Staphylococcus aureus* infection, or hypotension or when there has been recent prophylaxis with fluoroquinolones. Fungal, viral, and parasitic infections should also be considered as possible infectious causes of fever. Empiric coverage for these organisms is generally not provided unless there are history or examination findings suggesting such an infection. Colony-stimulating factors should be added only for critically ill patients with pneumonia, hypotension, or organ dysfunction.

CHEMOTHERAPY-INDUCED VOMITING AND DEHYDRATION

From the cancer patient's point of view, one of the most feared side effects of cancer treatment is nausea and vomiting. Promethazine or prochlorperazine are indicated for mild to moderate nausea and vomiting; for more severe cases, serotonin receptor antagonists such as ondansetron are given, as can high-dose metoclopramide. Additionally, the administration of dexamethasone in conjunction with metoclopramide or a serotonin receptor antagonist has been shown to significantly reduce nausea and emesis. For patients who are receiving the most emetogenic chemotherapeutic agents, neurokinin-1 receptor antagonists may be used in conjunction with serotonin receptor antagonists and dexamethasone.

HEMATOLOGIC MALIGNANCIES

Acute Leukemia

Acute leukemia develops as a result of alterations in the normal growth and development of hematopoietic cells. Populations of immature cells that are incapable of differentiating into mature,

functional hematopoietic cells are overproduced in the bone marrow, causing a reduction of normal red blood cells, neutrophils, and platelets. Leukemic patients therefore often present with symptoms related to pancytopenia, such as infection, anemia, and bleeding. Patients generally complain of weakness and fatigue and may have gingival bleeding, petechiae, ecchymoses, epistaxis, or menorrhagia and, less commonly, lymphadenopathy, splenomegaly, or bone tenderness. A provisional diagnosis can be made on the basis of a CBC with differential and a peripheral blood smear that shows blast cells constituting more than 5% of the circulating white cells. Possible morphologic features may include Auer rods, which are seen in acute myeloid leukemia. Definitive diagnosis and characterization of subtype is made by evaluation of the bone marrow.

Infection

The most common complication of leukemia seen in the ED is infection. When fever is present in a leukemic patient, a site of infection must be immediately and vigorously sought and the patient treated empirically with broad-spectrum antibiotics. Because most patients with leukemia tend to have qualitative defects of the circulating neutrophils, febrile patients should be presumed to be septic. Monotherapy using a broad-spectrum anti-pseudomal antibiotic (ceftazidime, meropenem, or cefepime), or dual therapy using an extended spectrum beta-lactam (piperacillin or ceftazidime) and an aminoglycoside, may be administered. There should be a low threshold for adding vancomycin in frequently hospitalized patients and in those with indwelling catheters.

Hemorrhage

Bleeding may occur from absolute thrombocytopenia or from coagulopathy associated with hematologic malignancies. Thrombocytopenic patients may develop petechiae and ecchymoses but typically do not suffer fatal hemorrhagic complications without first developing extensive mucous membrane bleeding such as

epistaxis, bleeding gums, hematuria, GI bleed, and/or bleeding from catheter or surgical sites. A threshold platelet count of 10,000/μL can be used to guide transfusion in patients with no signs of bleeding or just petechiae and ecchymoses. More aggressive therapy is indicated for active bleeding and in patients with risk factors such as fever, coagulation abnormalities, hyperleukocytosis, or recent minor surgery. The threshold in such patients should be at least 20,000/μL. Prophylactic transfusion to 50,000/μL to 100,000/μL is indicated for patients who are about to undergo a major invasive procedure. One unit of platelets usually raises the total platelet count by about 5,000/μL; platelet units are usually pooled in packs of five or six. Patients who have had previous transfusions may require HLA-matched platelets. Leukoagglutinin reaction, a common complication of transfusion that is manifested by fever, rigors, body aches, or shortness of breath, can be prevented or treated by giving acetaminophen and diphenhydramine prior to transfusion and using leukocyte-reduced blood products.

Disseminated intravascular coagulation (DIC) occurs not infrequently in this patient population. Some studies suggest that as many as 49% of cases of acute leukemia are complicated by DIC. DIC prolongs both the prothrombin and partial thromboplastin times, decreases fibrinogen levels, and increases the concentration of fibrinogen degradation products. Patients with DIC are at risk of complications from both increased clotting and bleeding (see Chapter 197). Treatment includes supportive management of coagulopathy until further treatment of the underlying malignancy can be given.

Hyperleukocytotic Syndrome

Hyperleukocytosis and leukostasis occur in acute leukemias as the total WBC count rapidly exceeds 50,000/μL to 100,000/μL and blood flow in the microcirculation becomes progressively impeded by the more rigid and adherent blast cell forms. There is local hypoxemia from the high metabolic activity of the leukemic cells, with resultant endothelial damage and hemorrhage. In chronic

myelogenous leukemia, a WBC count of >250,000/μL is often needed for leukostasis to occur, and problems related to leukostasis may not develop until the WBC count exceeds 1 million/μL.

Although the pulmonary and cerebral vascular beds are the most clinically relevant targets of leukostasis, the coronary circulation can also be affected as well as any other organ system. Cerebral involvement can range from very subtle confusion and somnolence to frank coma. Early pulmonary involvement presents with mild dyspnea and respiratory alkalosis. Typical chest x-ray findings include diffuse interstitial or alveolar infiltrates, but can be normal in early stages.

The management of hyperleukocytosis and leukostasis is centered on cytoreduction and maximizing vascular flow through supportive measures. Ideally, this is achieved by induction chemotherapy, which can dramatically reduce the WBC within 24 hours. As these patients are at very high risk for TLS, they should be closely monitored for electrolyte imbalance and treated prophylactically with allopurinol or rasburicase depending on renal function and fluid resuscitation. The use of leukapheresis is a widely accepted initial treatment but has never been shown convincingly to reduce the risk of developing leukostasis or to reduce early mortality. The urgent institution of induction chemotherapy is the most definitive therapy.

Hyperviscosity Syndrome

Hyperviscosity syndrome is seen in approximately half of patients with macroglobulinemia and in about 2% of the patients with multiple myeloma. The normal range of relative serum viscosity is 1.4 to 1.8. As values exceed 4, symptoms such as epistaxis, purpura, GI bleeding, visual impairment, and neurologic deficits begin to appear. For symptomatic patients, emergent plasmapheresis is necessary.

Polycythemia

Overproduction of erythrocytes or platelets may also precipitate medical emergencies. A hemoglobin level >17 g/dL, or a hematocrit >55% in women or 60% in men, may signal polycythemia vera, an uncontrolled clonal overproduction of erythrocytes. Other conditions that present with a high hematocrit include volume depletion, hypoxia, and polycythemia due to cigarette smoking or exposure to high altitudes. Patients with polycythemia vera are usually middle-aged and generally have a normal arterial oxygen saturation (>92%) and splenomegaly. They often have leukocytosis (>12,000 WBCs per &b.mu;L), as well as thrombocytosis (>400,000 platelets per &b.mu;L).

Emergencies due to polycythemia are related to hypervolemia and hyperviscosity. Patients may present with headache, vertigo, angina, or claudication. Other clinical features include generalized pruritus, especially after a shower or bath, and erythromelalgia (burning in the feet or hands with erythema). Thirty percent of patients with polycythemia vera suffer thrombotic episodes, and stroke is a common complication and cause of death. Elevated hematocrit findings can also interfere with platelet function; thus, some patients with uncontrolled polycythemia suffer hemorrhagic complications, most commonly in the GI tract. Many patients with polycythemia also have thrombocythemia (platelet counts >600,000/μL), a finding that is also associated with abnormal bleeding.

Polycythemic patients with signs or symptoms of hyperviscosity or thrombotic complications should have their blood volume and hemoglobin concentration reduced to normal as quickly as possible. Even without symptoms, a hemoglobin level of 18 g/dL, or a hematocrit 60% or higher, is also an indication for emergent phlebotomy or cytapheresis. Patients who are otherwise healthy can usually tolerate a rapid phlebotomy of 500 mL, although more gradual treatment may be required in the elderly or in those with known coronary artery disease. With the attainment of a normal hematocrit, the platelet defect that gives rise to thrombosis and bleeding is eventually corrected, but this can take weeks to occur. Elective surgery and dental procedures in polycythemic patients should thus be delayed until the red cell mass and platelet count

have been normalized for at least 2 months. Polycythemic patients in need of emergency surgery require emergent phlebotomy or cytapheresis. Low-dose aspirin should be administered if not contraindicated for other reasons. Antihistamines are indicated for pruritus. Other chemotherapeutic agents may be used with the guidance of a hematologist.

Thrombocytosis

Primary thrombocytosis, also known as essential thrombocytosis, is a subgroup of chronic myeloproliferative disorders in which there is chronic thrombocythemia that is not due to infection, inflammation, reactive thrombocytosis, or other myeloproliferative disorders. Patients do not usually become symptomatic or require treatment until the platelet count is >1,000,000/μL. Patients with a count >1.5 million/μL and age older than 60 are at higher risk.

About 25% to 50% of patients have splenomegaly and many have vasomotor symptoms or thrombohemorrhagic complications. Vasomotor manifestations include headache, lightheadedness, syncope, chest pain, acral paresthesia, visual disturbance, or erythromelalgia. Despite the high platelet count, patients may present with varying degrees of bleeding. Thrombotic events include strokes and transient digital ischemia. Treatment includes low-dose aspirin; other chemotherapeutic agents as hydroxyurea and anagrelide may be used with the guidance of a hematologist.

CRITICAL INTERVENTIONS

- Administer broad-spectrum antibiotics to patients with neutropenia and fever, after obtaining the appropriate cultures.
- Administer adequate analgesia for patients with severe pain related to oncologic conditions.
- Involve an oncologist or hematologist early in the course of treatment of the cancer patient.

Common Pitfalls

- Failing to recognize functional neutropenia, especially in cancer patients receiving chemotherapy.
- Failing to adequately treat pain and vomiting in patients receiving therapy.
- Failing to seek out treatable causes of mental-status changes or personality changes in cancer patients.
- Failing to recognize that back pain in a cancer patient may reflect SCC.
- Failing to adequately resuscitate patients who have significant therapeutic options and are not documented to have advanced refractory disease.

Endocrine and Metabolic Emergencies

Section Editor: JEFFREY J. SCHAIDER

CHAPTER 203 Acid–Base Disturbances

Robert Shesser

Severe acid–base disturbances, particularly those that develop rapidly, can be associated with diffuse cellular dysfunction and may require rapid treatment. Cerebral edema, seizures, cardiac dysrhythmias, and vascular dysfunction may result from an acid–base disturbance itself, from its underlying cause, or both. Precise analysis of a patient's acid–base status will help stratify disease severity, and help identify the disturbance's underlying cause(s). A thorough understanding of the principles of acid–base pathophysiology permits the physician to expand the diagnostic considerations from the history and physical examination to identify an additional, previously unsuspected disease process.

BASIC PHYSIOLOGY

Pure water at 25°C is a neutral solution with a pH of 7.0 and concentrations of both H^+ and OH^- of 100 mEq/L. Solutions of biologic importance share two important characteristics: They are all aqueous (water-based) and alkaline (greater concentration of OH^- than H^+ ions) (1). Plasma is a complex aqueous solution of a variety of electrolytes and proteins. Plasma's water component provides a limitless supply of hydrogen ion, but its H^+ concentration at any moment is determined by the relative concentrations of electrolytes, dissolved gas (primarily CO_2), and proteins that influence water's dissociation (1).

For the past century, pH, the logarithm of (1/hydrogen ion concentration), not the actual hydrogen ion concentration, has been used as the main clinical measure of acid–base status. The use of this

mathematically cumbersome surrogate marker arose because pH was the best measure obtainable by the available technology of the time. Cellular enzyme systems function optimally over a narrow range of hydrogen ion concentrations, and prolonged, significant deviations of hydrogen ion concentration from normal are not well tolerated (2). The body's homeostatic systems normally maintain a stable internal milieu, so any significant deviation from normal indicates the presence of disease (3).

For years, the Henderson–Hasselbach equation ($pH = pK \times \log HCO_3^- (0.03 \times pCO_2)$) has been viewed as the core concept governing clinical interpretation of acid–base balance (4,5). This model emphasizes the centrality of bicarbonate as a marker of the patient's metabolic status and considers changes in the nonvolatile buffers as effects rather than cause. The concept of base excess (BE) (or base deficit) was advanced as a way to quantitate the patient's metabolic acid–base status. Base excess was originally defined as the number of milliequivalents of acid (or alkali in the case of base deficit) required to return systemic pH to normal while maintaining the pCO_2 at 40 mm Hg at a temperature of 37°C. This model is useful in simple clinical situations, but fails because it assumes normal plasma proteins, perturbations of which can significantly affect the pH. The BE is also unable to identify situations with several coexisting metabolic acid–base disorders (4,6).

A more nuanced, but clinically complicated, model described by Stewart (4) posits that three independent variables determine the pH by influencing the degree that water dissociates into its components (H^+ and OH^-). The three variables are the strong ion difference (SID), the total weak acid concentration (A_{TOT}), and the dissolved carbon dioxide.

The Strong Ion Difference

The principle of electrical neutrality requires that equal numbers of ions with positive charge (cations) and ions with negative charge (anions) are dissolved in any solution. Dissolved ions differ in their tendency to be in either their completely dissociated (charged) form

or in a combination of charged and uncharged forms. The commonly measured electrolytes Na^+, Ca^{2+}, Mg^{2+}, K^+, Cl^-, etc., and lactate are said to be *strong ions,* meaning that they are fully dissociated in physiologic solutions (e.g., Na^+ and Cl^- do not exist in physiology solutions as uncharged NaCl). Weak ions, including plasma proteins, phosphate, NH_4^+, H^+, and HCO_3^-, are found in physiologic solutions in both their charged and uncharged forms. Although electroneutrality (the total number of cations and anions) is maintained at all times, there is normally a difference between the numbers of strong cations and strong anions in plasma. The SID is the sum of all the strong cations minus the sum of all strong anions. Its value is 40 to 42 mEq/L in healthy individuals with the difference represented by weak anions. Strong anions are conjugate bases (resulting from the addition of acids), and strong cations are conjugate acids (resulting from the addition of bases).

An increased SID from baseline results in a lower concentration of H^+ (alkalemia), and a decreased SID, an acidemia (6,7).

The Total Weak Acid Concentration

A less important metabolic determinant of plasma pH is A_{TOT}. Most of the weak acids are plasma proteins such as albumin, which can exist in their dissociated (A^-) form or undissociated (AH) forms, depending on the pH. Loss of weak acid from the plasma space (e.g., hypoalbuminemia, as seen in cirrhosis or nephrotic syndrome) raises pH independent of the pCO_2 and SID. Increased weak acids such as the hyperphosphatemia seen in renal failure help contribute to the metabolic acidosis seen in those patients. Normally, the kidney and intestines regulate the SID, whereas the liver is the primary regulator of A_{TOT} (4).

Dissolved Carbon Dioxide

About 220 mL/min of carbon dioxide is produced by cellular metabolism and by the interaction of bicarbonate and metabolic acids through carbonic anhydrase ($H^+ + HCO_3^- \leftrightarrow H_2CO_3 \leftrightarrow H_2O$

+ pCO_2). Cellular production accounts for the bulk of this (15,000 mM/d), which is more than 30 times the daily normal production of nonrespiratory acids. CO_2 is excreted via the lungs, which can increase minute ventilation to excrete large volumes of CO_2. Hyperventilation will remove H^+, providing an effective, open-ended, homeostatic mechanism to reduce the effects of endogenous or toxin-induced metabolic acidosis. Hyper or hypoventilation can also lead to acid–base changes from a primary disturbance of respiration.

The major differences between the Stewart and traditional model are as follows (8):

1. Bicarbonate is not always viewed as an independent variable that directly influences plasma hydrogen ion concentration (pH).
2. There is clearer acknowledgement of the obligatory dissociation of water into its component parts, its ability to provide a large supply of hydrogen ion, and the effect that other electrolytes have on water's dissociation.
3. Other plasma variables such as plasma proteins whose concentrations independently affect the pH are identified and quantified.

PATHOPHYSIOLOGY

Pathologic processes disturb the body's acid–base equilibrium either by adding to (or subtracting from) the body's soluble hydrogen ion activity (a metabolic disturbance) or through an increase or decrease in ventilation (a respiratory disturbance). The disruption of acid–base equilibrium by a single disease process is termed a *primary disturbance*. Any disruption initiates a series of compensatory responses that tend to return the pH toward normal. A compensatory response to a primary disturbance rarely returns the pH to the normal range and never overshoots the normal range (1,2).

The response to a primary metabolic disturbance is an initial, rapid adjustment of the respiratory rate (altering the pCO_2) followed by a slower renal adjustment mediated through changes in renal chloride excretion. In response to a metabolic acidosis, renal chloride ions are

excreted with ammonium (NH_4^+) (rather than Na^+ or K^+), which, because Cl^- is a strong cation and NH_4^+ is a weak anion, will increase the SID and raise the pH. In this clever manner, the kidney can regulate sodium balance (and thus intravascular volume) independently of chloride (9), which is central to renal response to metabolic acid–base perturbations.

The response to a primary respiratory disturbance relies exclusively upon renal adjustments of chloride excretion (*metabolic compensation*). As described in **Tables 203.1** and **203.2**, the relatively slow speed of the renal response to a primary respiratory disturbance allows clinical differentiation between *acute* respiratory disturbances and those processes that have been operative for several days which are termed *chronic*.

TABLE 203.1
Formulae Describing Expected Compensatory Response to Primary Acid–Base Disturbances

Simple Metabolic Acidosis
Predicted decreased pCO_2 mm Hg = $1.2 \times \Delta(HCO_3^-)$ mEq/L
Predicted pCO_2 mm Hg = $1.5(HCO_3^-)$ mEq/L + 8 ± 2
Anticipated pCO_2 approximates last two digits of arterial pH

Simple Metabolic Alkalosis
Predicted increased ΔpCO_2 mm Hg = $0.67 \times \Delta(HCO_3^-)$ mEq/L

Simple Acute Respiratory Acidosis
Predicted decreased ΔpH units = $0.8 \times \Delta pCO_2$ mm Hg
Predicted increased $\Delta(HCO_3^-)$ mEq/L = $0.1 \times \Delta pCO_2$ mm Hg

Simple Chronic Respiratory Acidosis
Predicted decreased ΔpH units = $0.3 \times \Delta pCO_2$ mm Hg
Predicted increased $\Delta(HCO_3^-)$ mEq/L = $0.35 \times \Delta pCO_2$ mm Hg

Simple Acute Respiratory Alkalosis
Predicted increased ΔpH units = $0.8 \times \Delta pCO_2$ mm Hg
Predicted decreased $\Delta(HCO_3^-)$ mEq/L = $0.2 \times \Delta pCO_2$ mm Hg

Simple Chronic Respiratory Alkalosis
Predicted increased ΔpH units = $0.17 \times \Delta pCO_2$ mm Hg
Predicted decreased $\Delta(HCO_3^-)$ mEq/L = $0.5 \times \Delta pCO_2$ mm Hg

TABLE 203.2
Primary Disturbances and Compensatory Responses in Terms of Changes in Carbonic Acid Constituents

	Usual pH	Hydrogen Ion Concentration	Serum Bicarbonate (Measured as Total CO_2 Content)	pCO_2
Metabolic acidosis	<7.38	Primary increase	Immediate decrease	Rapid compensatory decrease
Metabolic alkalosis	>7.42	Primary decrease	Immediate increase	Variable compensatory increase
Acute respiratory acidosis	<7.38	Secondary increase	Immediate small compensatory increase	Primary increase
Chronic respiratory acidosis	<7.38	Secondary increase	Slow larger compensatory increase	Primary increase
Acute respiratory alkalosis	>7.42	Secondary decrease	Immediate small compensatory decrease	Primary decrease
Chronic respiratory alkalosis	7.40–7.42	Secondary decrease	Slow larger compensatory decrease	Primary decrease

Although the degree and rapidity of compensatory responses to primary acid–base disturbances varies among patients, empiric data have defined a range of the expected compensatory response for each type of primary disturbance. Table 203.2 lists the anticipated compensatory responses for the different types of primary acid–base disturbances (5). Patients with profiles falling outside the predicted compensation range for a primary disturbance may have either a mixed disorder (wherein the primary disease process induces two distinct acid–base disturbances) or multiple primary disturbances from two or more independently acting disease processes.

Tables 203.3 and **203.4** list the causes of the primary and mixed acid–base disturbances most commonly seen in the emergency department (ED) patient. The emergency physician must be able to differentiate simple and mixed acid–base abnormalities and to identify and treat the underlying disease processes operative in a given patient.

TABLE 203.3
Causes of Primary Acid–Base Disturbances

Primary Metabolic Acidosis

Elevated anion gap (ACAT MUDPILES)
- Alcohol ketoacidosis
- Cyanide, CO
- Acetaminophen; antiretrovirals (NRTI)
- Toluene
- Methanol
- Uremia/renal failure
- Diabetic ketoacidosis/alcoholic ketoacidosis/starvation
- Paraldehyde/propylene glycol
- Iron/INH
- Lactic acidosis
- Ethylene glycol
- Salicylates

Normal anion gap (FUSED CRASH)
- Fistulas
- Uteroenteric conduits
- Saline
- Endocrine (hyperparathyroidism)
- Diarrhea
- Carbonic anhydrase inhibitor therapy
- Renal tubular acidosis
- Arginine/lysine/chloride (e.g., TPN)
- Spironolactone
- Hydronephrosis

Primary Metabolic Alkalosis

Vomiting/gastric suctioning

Volume depletion

Diuretic therapy

Corticosteroid therapy

Primary Respiratory Acidosis

CNS lesion

Sedative therapy/overdose

Neuropathies

Myopathies

Chest wall abnormalities
- Trauma
- Kyphosis

Pleural disease

Obstructive airway disease

Primary Respiratory Alkalosis

Anxiety

Progesterone therapy/increased exogenous progesterone

Sympathomimetic therapy

Fever

Hyperthyroidism

Hypoxia

Liver disease

CNS, central nervous system; INH, isoniazid; TPN, total parenteral nutrition.

TABLE 203.4
Mixed Acid–Base Disturbances

Metabolic Acidosis–Respiratory Alkalosis
Salicylate ingestion
Liver disease
Sepsis
Pulmonary embolism or pulmonary edema with hypotension
Pulmonary–renal syndrome
Metabolic Acidosis–Respiratory Acidosis
Cardiopulmonary arrest
Pulmonary edema
Drug overdose
Metabolic Alkalosis–Respiratory Alkalosis
Critical illness
Pregnancy
Mechanical ventilation-induced chronic hypercapnia
Metabolic Alkalosis–Respiratory Acidosis
Chronic hypercapnia with:
Diuretic overuse
Dehydration
Hypokalemia
Metabolic Acidosis–Metabolic Alkalosis
Diarrhea/vomiting
Organic acidosis/vomiting
Metabolic acidosis with excessive bicarbonate administration

ED EVALUATION

Acid–base disturbances should be suspected when a patient appears critically ill, has abnormal vital signs, respiratory rate, an abnormal mental status, and complains of vomiting, diarrhea, or changes in urine output. A blood gas and complete serum electrolytes (including albumin and phosphate) should be obtained. A venous blood gas suffices for measuring the pH and pCO_2 for acid–base analysis purposes in most clinical situations.

A thorough clinical evaluation is mandatory before considering the acid–base status, because the physician must first formulate a set of preliminary hypotheses about the disease processes most likely and

then analyze the patient's observed acid–base parameters. The physician should then ask three questions:

1. Does the patient have an acidemia or an alkalemia? *Acidemia* is defined as a pH <7.38 and *alkalemia* as a pH >7.42. An *acidosis* is any process that causes acid to accumulate, whereas an *alkalosis* is a process that causes hydrogen ion depletion. If the patient is acidemic, at least one of the processes present should be an acidosis.
2. Is the primary disturbance respiratory or metabolic? Look at the serum bicarbonate, BE, and pCO_2. Patients with a primary metabolic acidosis have a low bicarbonate, negative BE, and a pCO_2 below normal. Similarly, patients with a primary respiratory disturbance have an abnormal pCO_2 with a pH that varies with the disease's chronicity (Table 203.5).

TABLE 203.5
Respiratory Versus Metabolic Acidosis/Alkalosis

	pH	pCO_2	HCO_3
Metabolic acidosis	Decrease	Decrease	Decrease
Metabolic alkalosis	Increase	Increase	Increase
Respiratory acidosis	Decrease	Increase	Increase
Respiratory alkalosis	Increase	Decrease	Decrease

3. Is the acid–base disturbance primary or nonprimary? To identify a multiple or mixed disturbance, the physician should compare the observed parameters to a series of formulae that quantify the compensatory responses anticipated for any primary disturbance. When the appropriate formula (see Table 203.1) is applied, a significant deviation from the anticipated compensatory response parameters suggests the presence of either a mixed disorder or two primary disorders. These formulas were developed in populations that had been in a steady state for 12 to 24 hours (5). Accordingly, the emergency physician should avoid the rigid application of these formulas in situations where the clinical situation is rapidly changing.

Metabolic Acidosis and Anion Gap(s)

Primary metabolic acidosis is the most common acid–base disturbance in hospitalized patients and is often present in ED patients (14). Calculation of the *anion gap,* defined as (sodium + potassium) − (chloride + CO_2 content), is used to develop the differential diagnosis of the various causes of a metabolic acidosis (described in Table 203.3) allowing the clinician to divide the causes of primary metabolic acidoses into those with either a normal or elevated anion gap. As plasma's electric neutrality is always maintained, there are always equal numbers of cations and anions. The term "gap" is a misnomer because the "gap" is the difference between the cations and anions that are measured by commonly used clinical laboratory assays. The normal range for the anion gap is 5 to 12 ± 3 mEq/L (2).

Typically, cation concentrations are more tightly regulated and anion concentrations have a greater tendency to fluctuate. Decreased plasma proteins (mainly albumin) and phosphate concentrations (both anions) are frequently seen in critically ill patients. Their decrease would tend to artificially decrease the anion gap and might therefore artifactually mask an anion gap created by an organic acid accumulation caused by a disease process. The anion gap correction for hypoalbuminemia would be as follows:

$$AG_{corr} = AG_{calculated} + 2.5\ (\text{reference albumin-measured albumin})\ (6,7)$$

Increases or decreases of serum phosphate have the same effect as changes in albumin concentration on the anion gap.

An elevated anion gap, primary metabolic acidosis, results from an excess of either endogenous or exogenous organic acids. A moderate increase in the anion gap (12 to 20 mEq/L) may be seen in situations other than a metabolic acidosis, including dehydration, spurious laboratory values, and treatment with citrate, lactate, or certain antibiotics. In cases of slight anion gap increase, the clinician must confirm the presence of a metabolic acidosis by analyzing the pH and pCO_2. Anion gaps >25 mEq/L most often indicate a severe condition such as ketoacidosis, lactic acidosis, or the toxin-associated acidoses

(10). In these cases, the pH and pCO_2 should be checked to assess the severity of the academia and adequacy of respiratory response.

Strong Ion Gap

There has been much concern in the critical care literature that diagnostic reliance on either the BE or standard anion gap may fail to identify some critically ill patients. The Stewart system describes a *Strong Ion Gap (SIG)* which provides the clinician with another tool to identify patients with organic metabolic acidosis where elevated concentrations of unmeasured strong anions such as lactate, formate, ketoacids, or salicylate may be present (8) (Fig. 203.1). This "gap" can be calculated from the results of tests that are available on most critical care patients. The data needed to calculate the SIG include Na^+, K^+, Ca^{2+}, Mg^{2+}, Cl^-, CO_2 content, albumin, and phosphates.

$$SIG = SID_{app} - SID_{eff} = XA^-$$

$$SID_{app} = Na^+ + K^+ + Ca^{2+} + Mg^{2+} - Cl^-$$

$$SID_{eff} = HCO_3^- + 0.28\ (\text{albumin g/L}) + 1.8\ (PO_4^-)$$

FIGURE 203.1 Strong ion gap formula.

The SIG is calculated as the difference between the apparent strong ion difference (SID_a) = ($Na^+ + K^+ + Ca^{2+} + Mg^{2+}$) − ($Cl^-$) and the effective strong ion difference (SID_e) that is estimated as (HCO_3^-) + 0.28 (albumin [g]/L]) + 1.8 (phosphate [mmol/L]). The SIG would then be equal to the plasma concentration of organic acids: $XA^- = SIG = SID_a - SID_e$. The SIG is normally 0. Readers should note that the SIG and SID are two very different measurements. An increased SIG is indicative of an organic acid-induced metabolic acidosis and actually results from a decrease in the SID. The SIG has been suggested to be a superior predictor of mortality than the standard anion gap (2).

The serum potassium level should rapidly be assessed in all patients with a suspected metabolic acidosis by seeking electrocardiographic evidence of hyperkalemia and ordering a

bedside electrolyte analysis. In general, the serum potassium level increases as a patient becomes more acidemic. This increase may result from the interaction of the excess hydrogen ion with intracellular buffer systems (11). There is no completely reliable formula to estimate the expected change in serum potassium arising from a given change in pH. Inorganic acidoses (hydrochloric acid, toxins) tend to increase the serum potassium more than organic acidoses such as ketoacidosis and lactic acidosis (1).

Primary Metabolic Alkalosis

Metabolic alkalosis results in an elevated serum bicarbonate and increased SID. Most metabolic alkaloses are initiated by a combination of volume, potassium, and chloride depletion. Patients with mild metabolic alkalosis generally require both normal saline and potassium chloride administration to correct the acid–base disturbance.

The ventilatory response to metabolic alkalosis is severely limited the patients defense against hypoxia since it would require that the patient hypoventilate. Most of the compensatory responses to a primary metabolic alkalosis would therefore be renal, and the kidney cannot alkalize the urine if the patient is hypokalemic or significantly volume-depleted (12). Metabolic alkaloses, therefore, tend to be self-perpetuating if not treated by aggressive rehydration and potassium administration (5).

Patients with a pH >7.6 from metabolic alkalosis are at risk for cardiovascular and cerebrovascular ischemia and hypoventilation and require rapid reduction of the serum bicarbonate to <40 mmol/L. The most common causes of this condition are chloride-responsive and include loss of gastric acid and loop diuretics (11). Severe metabolic alkalosis often leads to a decrease in bicarbonate's space of distribution (contraction alkalosis) resulting in high extracellular bicarbonate levels in the presence of massive peripheral edema and total body chloride depletion.

Primary Respiratory Disturbances

Primary respiratory abnormalities are classified according to their duration as “acute” or “chronic.” Because the renal compensatory process is delayed by 48 to 72 hours, patients with primary acute respiratory disturbances experience a larger change in pH for a given change in pCO_2 than do patients with primary chronic respiratory disturbances. Chronic respiratory alkalosis is alone among the primary acid–base disturbances in that the compensatory renal response will sometimes return the pH into the normal range (5).

The immediate treatment of a severe, primary respiratory disturbance involves a mechanical airway intervention, such as increasing ventilation in respiratory acidosis or decreasing the minute ventilation for patient with respiratory alkalosis who are being mechanically ventilated. Longer-term treatment involves identifying and treating the disturbance’s underlying cause. The physician must avoid a treatment that suddenly normalizes the pCO_2 in a patient with chronic respiratory disturbance. In instances where renal compensatory mechanisms have corrected the pH, rapid normalization of the respiratory parameters risks a dangerous overshooting of pH until the kidneys adapt to the new respiratory situation.

Patients with respiratory acidosis require emergent intervention, because the increase in pCO_2 can cause life-threatening acidemia and increased somnolence (CO_2 narcosis) (13). A blood gas determination is mandatory for patients with abnormal mental status, especially if they manifest any history of or clinical evidence of ventilatory dysfunction.

Acute respiratory alkalosis is the most common primary respiratory acid–base disorder in emergency practice being caused by such common conditions as fever, anxiety, or pregnancy. Although this acid–base abnormality requires treatment infrequently, its presence may require a search for its underlying cause.

Multiple Acid–Base Disturbances

When multiple acid–base disturbances are present, the patient may be acidemic, alkalemic, or have a “normal” pH. Most combinations

of primary acid–base disturbances can be seen clinically. As mentioned above, clinical context should be established before performing the analysis to search for the presence of a mixed or multiple primary disturbances.

Metabolic acidosis with respiratory acidosis or alkalosis is diagnosed when the pCO_2 deviates significantly from that predicted (see Table 203.1) for a primary metabolic acidosis. Combined metabolic acidosis and respiratory acidosis is seen in situations such as cardiac arrest or the postictal state, in which the pCO_2 is either normal, above normal, or the decrease is less than would be predicted for the degree of metabolic acidosis. Combined metabolic acidosis and respiratory alkalosis are commonly noted in salicylate poisoning, where the salicylate (an exogenous organic acid) causes a metabolic acidosis and while directly stimulating the brainstem to increase ventilation more than would occur from the compensatory response along to the metabolic acidosis.

One should be cautious in diagnosing the presence of mixed or multiple disturbances in patients with a rapidly changing clinical status, because the formulae for the expected responses were derived from patients in a steady state. Thus, there is an increased chance of over-diagnosing multiple disorders in an acutely ill patient with a changing clinical situation (5).

The combination of *metabolic acidosis* and *metabolic alkalosis* is seen in a patient with a relatively normal pH and an anion gap elevation significantly greater than the decrease in bicarbonate from normal (14). A common example of this mixed disturbance is the patient with alcoholic ketoacidosis who has been vomiting or a patient with both vomiting and diarrhea. The presence of a mixed or multiple acid–base disturbance may become evident only after one of the deficits is corrected. In the vomiting and diarrhea example, rapid volume correction with normal saline but without concomitant bicarbonate replacement will “unmask” the metabolic acidosis, with the serum bicarbonate decreasing as volume is restored.

CONTROVERSIES IN MANAGEMENT OF METABOLIC ACIDOSES

The rationale for aggressive treatment of metabolic acidosis with exogenously administered alkaline therapy (most frequently sodium bicarbonate) is that the acidosis per se disrupts cellular function and can lead to decreased cardiac contractility, predisposition to cardiac arrhythmias, peripheral vasodilation, impairment in glucose regulation, and stimulation of inflammatory mediators (8). The presumption of treatment benefit is based primarily on extrapolation from animal studies from which expert recommendations have been derived in the absence of good human treatment data. There is greater concordance among physicians about the benefits of chronic alkali administration to patients with normal anion gap (hyperchloremic) acidosis, particularly those that result from chronic renal bicarbonate loss. Treatment of the underlying disorder in both lactic acidosis and ketoacidosis can rapidly replenish bicarbonate stores.

Diabetic Ketoacidosis

Insulin administration, rehydration, and close monitoring and replacement of potassium are the mainstays of emergent therapy of diabetic ketoacidosis (DKA), and little benefit has been documented from adding bicarbonate to this regimen. Adverse effects of excessive bicarbonate administration in DKA include tissue hypoxia from bicarbonate's leftward shift of the oxyhemoglobin dissociation curve; augmentation of hepatic ketogenesis; hypertonicity and sodium overload; hypokalemia; and late alkalemia, when bicarbonate is regenerated from ketoacids (15). Some patients have deteriorated after aggressive bicarbonate treatment from either a "paradoxical" central nervous system acidosis (15), as bicarbonate does not cross the blood–brain barrier, or cerebral edema from activation of a membrane Na^+–H^+ exchanger by the organic acidosis (16). A recent study showed no benefit from bicarbonate administration in patients with a pH <6.9 (17).

Sepsis and Lactic Acidosis

Most patients with lactic acidosis have either tissue hypoxia leading to lactate overproduction (e.g., hypoperfusion, sepsis, cyanide poisoning, etc.) or the inability to metabolize tissue-generated lactate as seen in patients with liver disease. Bicarbonate therapy is not recommended and may be dangerous in hypoperfusion-induced lactic academia (18). In other cases of lactic acidosis, such as that induced by metformin, bicarbonate therapy may be indicated in patients with very severe acidemia. Common causes of lactic acidosis are listed in Table 203.6.

TABLE 203.6
Common Causes of Lactic Acidosis

Hypotension
Sepsis
Methanol, ethylene glycol
Metformin, nitroprusside, beta-agonist, reverse transcriptase inhibitors
Diabetes mellitus
Alcoholism
Congenital
Thiamine deficiency
Short bowel syndrome
Hematologic malignancies

The treatment of patients with lactic acidosis should focus on improvement of tissue oxygenation and identification and treatment of its underlying cause. As a temporizing measure in the presence of severe lactic acidemia (pH <7.0), 1 to 2 mEq/kg of bicarbonate can be administered by slow infusion, with frequent re-evaluation of the clinical and metabolic situation (6).

Emergency physicians should be aware of cases of potentially life-threatening lactic acidosis in HIV patients taking nucleoside-analog reverse transcriptase inhibitors.

Cardiac Arrest

Neither animal nor human data have demonstrated the effectiveness of bicarbonate in increasing survival after cardiac arrest, and there have been reports of severe hyperosmolality, alkalosis, hypernatremia, and even pediatric intracerebral hemorrhage from injudicious bicarbonate administration.

The 2010 American Heart Association's *Advanced Cardiac Life Support* guidelines (19) support the use of bicarbonate in critically ill patients with a pre-existing metabolic acidosis, hyperkalemia, or tricyclic overdose but not in the "undifferentiated" cardiac arrest patient.

Toxin-Induced Acidosis

Methanol and ethylene glycol are two low–molecular-weight alcohols that produce severe metabolic acidoses when ingested. Parenteral sodium bicarbonate is recommended as an adjunctive therapy because the organic acids generated in these poisonings cannot be converted back to bicarbonate by the liver.

The physician should administer 1 to 2 mEq/kg of bicarbonate to patients with pH <7.10 (<7.2 if the patient has underlying cardiovascular disease) by isotonic drip at a rate of 0.1 mEq/kg/min, and gauge the quantity and frequency of further doses by the response. Definitive treatment includes administration of ethanol or 4-methylpyrazole (fomepizole, Antizol) to delay the formation of toxic intermediates, as well as hemodialysis for removal of the ingested alcohol and its toxic metabolites. In these intoxications, elevations in the anion and osmolar gaps may not be present simultaneously. Patients may present initially with only an elevated osmolar gap, and then the anion gap increases as alcohol is metabolized into a variety of intermediate forms (20).

Salicylate ingestion produces a characteristic picture of metabolic acidosis–respiratory alkalosis. Unless the serum is highly alkaline, judicious administration of sodium bicarbonate to alkalinize the urine, while keeping the blood pH <7.50, will trap the salicylate ion in the renal tubules. With the addition of forced diuresis, urinary alkalinization will enhance excretion of the ingested salicylate.

CRITICAL INTERVENTIONS

- Rapidly test the serum potassium level and place all patients with potential, severe acid–base changes on a continuous cardiac monitor.
- Arterial or venous blood gasses and standard serum electrolytes will suffice to diagnose most acid–base abnormalities.
- Initially evaluate the patient and determine the most likely condition(s) present; by analyzing a discordance between the patient's actual acid–base status and the acid–base changes that should result from the suspected conditions, the clinician can expand the differential diagnosis and identify hitherto unsuspected conditions.

Common Pitfalls

- In a patient with a chronic respiratory acidosis, avoid rapid normalization of the pCO_2, as this may lead to a dangerous overshoot alkalosis.
- Use caution in diagnosing mixed disturbances in patients with a rapidly changing clinical status. The formulas for the expected response to primary acid–base disturbances were developed in patients who had achieved a steady state.
- Be sure to check the pCO_2 in all appropriate patients with abnormal mental status.

CHAPTER 204 Diabetes Mellitus

Scott R. Votey and Anne L. Peters

Diabetes affects an estimated 8.3% of the US population, or approximately 25.8 million people (1), and this is expected to rise to 33.5 million by 2050 (2). Management of diabetes and its complications is disproportionately resource-intensive. In 2012, the per-capita cost of health care was $13,741 for people with diabetes as compared to $3,495 for those without the disease. The emergency department (ED) utilization rate by people with diabetes is twice that of the unaffected population (3). This chapter focuses on the ED evaluation and treatment of the acute and chronic complications of diabetes other than those directly associated with hypoglycemia and severe metabolic disturbances.

Approximately 90% of patients with diabetes have type 2 (or ketosis-resistant) diabetes (T2DM), and the remainder have type 1 (ketosis-prone) diabetes (T1DM). Although the pathophysiology of the disease differs between the types of diabetes, most of the complications, including microvascular, macrovascular, and neuropathic, are similar regardless of the type of diabetes.

Microvascular complications of diabetes include retinopathy and nephropathy. Macrovascular complications are peripheral vascular, cerebrovascular, and coronary artery disease (CAD). Hypertension eventually occurs in approximately 50% of patients with diabetes. Chronic, poorly controlled hyperglycemia, in addition to the metabolic consequences associated with glycosuria, can lead to impaired immune function and delayed wound healing. The development of complications is related to the duration of diabetes and the degree of glycemic control.

ED EVALUATION

In addition to the history and physical examination related to the presenting complaint, the assessment of patients with diabetes includes the following.

History

Type of Diabetes

Type 1 diabetes mellitus (T1DM) generally occurs in younger, lean patients and is characterized by an autoimmune process that leads to the marked inability of the pancreas to secrete insulin (Table 204.1). The distinguishing characteristic of a patient with T1DM is that if insulin is withdrawn, ketosis, and eventually ketoacidosis, develops. These patients are therefore insulin-dependent (i.e., insulin is life-sustaining), because they produce no endogenous insulin. Although the onset of T1DM often occurs in childhood, 30% of patients with new-onset T1DM are older than 18 years of age. In adults, T1DM tends to have a slower course to total islet-cell failure than it does in children. In addition, rates of obesity in individuals with type 1 diabetes are similar to that in the general population, which means that among adults, one-third is normal weight, one-third is overweight, and one-third obese. Newer antibody tests have allowed for the identification of more people with this slower-onset adult form of T1DM, which has been called *latent autoimmune diabetes of the adult* (LADA).

TABLE 204.1
Metabolic and Clinical Characteristics of the Two Major Types of Diabetes Mellitus

Characteristic	Type 1 Diabetes (T1DM)	Type 2 Diabetes (T2DM)
Synonyms	Juvenile-onset diabetes, IDDM	NIDDM
Age of onset	Usually <30 yrs; up to 30% present above the age of 18	Usually >40 yrs; sometimes in younger persons, even children
Genetic predisposition	Moderate (requires environmental factor[s] for expression); only 50% of identical twins develop DM1 if one sibling affected	A strong family history of T2DM and Hispanic, African American, or Native American heritage make the diagnosis of type 2 diabetes more likely, regardless of age 80–100% of identical twins develop DM2 if one sibling is affected
Precipitating factors	Viral/toxic/other trigger precipitating autoimmune response	Obesity, age, inactivity
Findings at diagnosis	Antibodies include ICA-512, IA2, insulin and zinc transporter 8 (ZnT8) at diagnosis in children. Positive anti-GAD antibodies in adults	Most patients had asymptomatic diabetes for 4–7 yrs prior to "diagnosis"
Endogenous insulin levels	Very low to none. Measurable initially, undetectable over time	Present
Insulin resistance	Can be present if genes for type 2 diabetes, obesity, infection	Present
Response to prolonged fast	Hyperglycemia, ketoacidosis	Normal blood glucose levels
Response to stress, withdrawal of insulin	Ketoacidosis	Hyperglycemia without ketosis
Response to diet alone	Negligible	Always present to some degree

IDDM, insulin-dependent diabetes mellitus; NIDDM, non–insulin-dependent diabetes mellitus; ICA, islet cell antibody.

Type 2 diabetes mellitus (T2DM) typically occurs in older (>40 years of age) patients who have a family history of diabetes. However, T2DM is occurring in younger and younger individuals. Children as young as 2 years old have been diagnosed with T2DM, and increasingly teenagers of Hispanic, Native American, and African American descent are developing prediabetes and diabetes (4). Patients who develop T2DM have a genetic predisposition to do so and develop insulin resistance along with insufficient pancreatic β-cell secretion of insulin. Most patients (90%) who develop T2DM are obese, and obesity itself is associated with insulin resistance, which further worsens the diabetic state. Because patients with T2DM retain the ability to secrete some endogenous insulin, those who take insulin rarely develop diabetic ketoacidosis (DKA) when insulin is stopped. Therefore, they are considered insulin-requiring, not insulin-dependent. Moreover, patients with T2DM often do not require treatment with oral or injectable antidiabetic medication if they lose weight.

Differentiating between the two types of diabetes on the basis of age has become less reliable and cannot always be done in the ED, but a good clinical history often allows the distinction to be made. A strong family history of T2DM, obesity, and Hispanic, African American, or Native American heritage all make the diagnosis of type 2 diabetes more likely, regardless of age.

The presence of anti-GAD65 antibodies confirms the diagnosis of T1DM, and the presence of an elevated or even normal C-peptide

level in patients who have been treated with insulin for several years confirms a diagnosis of T2DM. The presence of measurable C-peptide levels at the time of diagnosis is not usually helpful as C-peptide levels can be elevated or absent in both new-onset type 1 and type 2 diabetes, depending on the level of hyperglycemia and other clinical circumstances. Although neither of these tests is likely to be available on a stat basis in the ED, an understanding of their results may be useful to emergency physicians. When in doubt, use insulin therapy as needed in the ED and defer to the patient's primary care provider to follow up on testing and diagnosis.

Duration of the Diagnosis of Diabetes

The chronic complications of diabetes are related to the length of time the patient has had the disease. Patients with T2DM have often had diabetes for 5 to 7 years before the diagnosis is made and can present with the complications of diabetes at the time of diagnosis (5).

Blood Glucose Levels

Patients should be asked if they self-monitor their blood glucose levels and what their usual and recent blood glucose levels have been. Recent changes in the frequency of high and low blood sugar levels should be noted.

Diabetes Medications

Patients should be asked the names and doses of their diabetes medications. A sense of patients' level of knowledge about managing their diabetes is useful, as it may indicate their degree of adherence with their treatment plan.

Hemoglobin A1c Level

The date and value of the most recent level is a useful indicator of both the quality of glycemic control and the patients' monitoring of their disease.

Symptoms of Diabetes

Symptoms of hyperglycemia (polyuria, polydipsia, nocturia, weight loss) and hypoglycemia (see Chapter 206) should be elicited, with their time course and severity.

Complication of Diabetes

Although complications are often diagnosed by physical examination or by laboratory testing, the presence of known complications of diabetes should also be sought in the history: retinopathy, nephropathy, vasculopathy (hypertension and coronary, peripheral, and cerebrovascular disease), neuropathy, or diabetic foot complications (ulcers and amputations).

Physical Examination

Vital Signs

Orthostatic vital signs may be useful in assessing volume status and in suggesting the presence of an autonomic neuropathy. If the respiratory rate and pattern suggest Kussmaul breathing, DKA must be immediately considered and appropriate tests ordered.

Fundoscopy

Include a careful view of the retina, visualizing both the optic disc and the macula. If hemorrhages or exudates are seen, the patient should be seen by an ophthalmologist as soon as possible. Nonophthalmologists tend to underestimate the severity of retinopathy, especially if the pupils have not been dilated. In general, if patients have not been seen by an ophthalmologist within the past year, they should be encouraged to follow up for an annual retinal examination.

Foot Examination

Foot deformity and abnormal nails can be a sign that follow-up with a podiatrist is needed and attention given to foot care. The dorsalis pedis and posterior tibialis pulses should be palpated and their presence or absence noted. This is particularly important among patients with foot infection, because poor lower-extremity blood flow can delay healing and increase the risk of amputation. Documenting lower-extremity sensory neuropathy is also useful, because decreased sensation limits the patient's ability to protect the feet and ankles. If peripheral neuropathy is found, the patient should be made aware that foot care (including daily foot examinations) is very important

for the prevention of foot ulcers and possible subsequent lower-extremity amputation.

DIABETES MEDICATIONS

The number and variety of medications available for the treatment of diabetes, particularly T2DM, continues to increase (Table 204.2). These drugs allow for the use of combination oral therapy, including the combination oral agents plus a noninsulin injectable and the combinations of nearly any oral or noninsulin injectable with insulin (6,7).

TABLE 204.2
Properties of Currently Available Glucose Lowering Agents Used in the Treatment of Patients with Type 2 Diabetes Mellitus

Class	Compound(s)	Cellular Mechanism	Primary Physiologic Action(s)	Advantages	Disadvantages	Cost
Biguanides	• Metformin	Activates AMP-kinase	• ↓ Hepatic glucose production	• Extensive experience • No weight gain • No hypoglycemia • Likely ↓ CVD events (UKPDS)	• Gastrointestinal side effects (diarrhea, abdominal cramping) • Lactic acidosis risk (rare) • Vitamin B_{12} deficiency • Multiple contraindications: CKD; acidosis, hypoxia, dehydration, etc.	Low
Sulfonylureas	• Glibenclamide/ Glyburide • Glipizide • Gliclazide[a] • Glimepiride	Closes K_{ATP} channels on β-cell plasma membranes	• ↑ Insulin secretion	• Extensive experience • ↓ Microvascular risk (UKPDS)	• Hypoglycemia • Weight gain • Blunts myocardial ischemic preconditioning • Low durability	Low
Meglitinides (Glinides)	• Repaglinide • Nateglinide	Closes K_{ATP} channels on β-cell plasma membranes	• ↑ Insulin secretion	• Postprandial glucose control • Dosing flexibility	• Hypoglycemia • Weight gain • Blunts myocardial ischemic preconditioning • Frequent dosing schedule	High
Thiazolidinediones	• Pioglitazone • Rosiglitazone[b]	Activates the nuclear transcription factor PPAR-γ	• ↑ Insulin sensitivity	• No hypoglycemia • Durability • HDL-C • Triglycerides (pioglitazone) • ↓ CVD events (ProACTIVE, pioglitazone)	• Weight gain • Edema/heart failure • Bone fractures • LDL-C (rosiglitazone) • ↑ MI (meta-analyses, rosiglitazone) • ↑ Bladder cancer (pioglitazone)	High[c]
α-glucosidase inhibitors[d]	• Acarbose • Miglitol	Inhibits intestinal α-glucosidase	• Slows intestinal carbohydrate digestion/absorption	• Nonsystemic • Postprandial glucose • ↓ CVD events (Stop-NIDDM)	• Generally modest A1c efficacy • Gastrointestinal side effects (flatulence, diarrhea) • Frequent dosing schedule	Moderate
DPP-4 inhibitors	• Sitagliptin • Vildagliptin[d] • Saxagliptin • Linagliptin	Inhibits DPP-4 activity, increasing postprandial active incretin (GLP-1, GIP) concentrations	• Insulin secretion (glucose-dependent) • ↓ Glucagon secretion (glucose-dependent)	• No hypoglycemia • Well tolerated	• Generally modest A1c efficacy • Urticaria/angioedema • Pancreatitis	High
GLP-1 receptor agonists	• Exenatide • Exenatide extended release • Liraglutide	Activates GLP-1 receptors	• Insulin secretion (glucose-dependent) • Glucagon secretion (glucose-dependent) • Slows gastric emptying • ↑ Satiety	• Weight reduction • Potential for improved β-cell mass/function (preliminary data) • Cardiovascular protective actions	• Gastrointestinal side effects (nausea/vomiting) • Acute pancreatitis • C-cell hyperplasia/ medullary thyroid tumors in animals (liraglutide) • Injectable • Training requirements	High
SGLT2 inhibitors	• Canagliflozin	Inhibits sodium-glucose cotransporter 2 (SGLT2)	• Blocks glucose reabsorption in renal tubules increasing glycosuria	• Reduction in plasma glucose levels • Possibly results in weight loss	• Risk for urinary tract infection • ↑ Vaginal and penile fungal infections • Dehydration • Electrolyte disturbances • ↑ Serum creatinine levels	
Bile acid sequestrants[d]	• Colesevelam	Binds bile acids in intestinal tract, increasing hepatic bile acid production; activation of farnesoid X receptor (FXR) in liver	• Unknown • ↓ Hepatic glucose production • ↑ Incretin levels	• No hypoglycemia • ↓ LDL-C	• Generally modest A1c efficacy • Constipation • Triglycerides • May ↓ absorption of other medications	High

Class	Compound(s)	Cellular Mechanism	Primary Physiologic Action(s)	Advantages	Disadvantages	Cost
Dopamine-2 agonists[d]	• Bromocriptine (quick-release)[e]	Activates dopaminergic receptors	• Modulates hypothalamic regulation of metabolism • ↑ Insulin sensitivity	• No hypoglycemia • ↓ CVD events (Cycloset Safety Trial)	• Generally modest A1c efficacy • Dizziness/syncope • Nausea • Fatigue • Rhinitis	High
Amylin mimetics[d]	• Pramlintide[e]	Activates amylin receptors	• Glucagon secretion • Slows gastric emptying • ↑ Satiety	• Dampens PPG excursions • Weight reduction	• Generally modest A1c efficacy • Gastrointestinal side effects (nausea/vomiting) • Hypoglycemia unless insulin dose is simultaneously reduced • Injectable • Frequent dosing schedule	High
Insulins	• Human NPH • Human regular • Lispro • Aspart • Glulisine • Glargine • Detemir • Premixed (several types)	Activates insulin receptors	• Glucose disposal • ↓ Hepatic glucose production	• Universally effective • Theoretically unlimited efficacy • ↓ Microvascular risk (UKPDS)	• Hypoglycemia • Weight gain • Mitogenic effects • Injectable • Training requirements • "Stigma" (for patients)	Variable[f]

AMP, adenosine monophosphate; CVD, cardiovascular disease; CKD, chronic kidney disease; UKPDS, United Kingdom prospective diabetes study; PPAR, peroxisome proliferator-activated receptor; HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol; ProACTIVE, prospective pioglitazone clinical trial in macrovascular events; DPP-4, dipeptidyl peptidase-4; GLP-1, glucagon-like peptide-1.
[a]Not licensed in the United States.
[b]Prescribing highly restricted in the United States.
[c]To be available as a generic product in 2012, with expected significant reductions in cost.
[d]Limited use in the United States/Europe.
[e]Not licensed in Europe.
[f]Depends on type (analogs >> human insulins) and dosage.
Modified from ADA/EASD guidelines.

The biguanides (e.g., metformin) primarily decrease hepatic glucose production and may also slightly lower insulin resistance. These drugs commonly cause nausea, abdominal cramping, and diarrhea. Rarely, they can cause severe lactic acidosis, especially among patients with renal insufficiency.

The sulfonylurea agents (e.g., glyburide, glipizide, glimepiride) and meglitinides (e.g., repaglinide and nateglinide) increase insulin secretion and are considered long- and short-acting insulin secretagogues, respectively. Their most common serious adverse reaction is hypoglycemia, which can be severe and may limit use of these agents.

The thiazolidinediones (rosiglitazone and pioglitazone) act as insulin sensitizers. Both increase plasma volume and can cause fluid retention. The most common side effect is mild-to-moderate pedal edema. Both can result in congestive heart failure (CHF) in patients who are at risk. The thiazolidinediones should not be used in patients with CHF and in patients who have a baseline alanine

aminotransferase three times the upper limit of normal. Pioglitazone and rosiglitazone differ in terms of their effect on lipids (pioglitazone decreases triglyceride levels and raises high-density lipoprotein (HDL) levels; rosiglitazone causes a lesser increase in HDL cholesterol levels and has no effect on triglyceride levels). Rosiglitazone may cause an increased risk of myocardial infarction (MI) and heart-related deaths (8) and is only available as a restricted use agent. Pioglitazone appears to be safe from a cardiovascular event perspective (9). Finally, thiazolidinediones increase the risk of bone fracture and should be used with caution in individuals with advanced osteoporosis.

The α-glucosidase inhibitors (e.g., acarbose and miglitol) decrease intestinal absorption of carbohydrate, often producing flatulence and, rarely, causing small bowel obstruction. These agents produce a relatively small fall in A1c (approximately 0.5% compared to 1% to 2% for most other agents). They are most effective in patients consuming a high carbohydrate diet and are commonly used in Asia, where rice is a staple.

Dipeptidyl peptidase-4 (DPP-4) inhibitors increase circulating levels of GLP-1 (glucagon-like peptide-1), which is an incretin hormone secreted from the gut that helps improve insulin secretion and lower blood sugar levels. There are four available DPP-4 inhibitors: Sitagliptin, saxagliptin, linagliptin, and alogliptin. All except for linagliptin must be dose reduced for renal dysfunction.

Glucagon-like peptide receptor agonists (GLP-1 RAs) are injectable agents that directly act upon GLP-1 receptors. These agents tend to cause a greater HbA1c lowering than DPP-4 inhibitors and often cause weight loss, owing to an increase in satiety. Currently marketed agents include short-acting exenatide (given twice daily), long-acting exenatide (given once weekly) and liraglutide (once daily). GLP-1 RAs commonly cause nausea, vomiting, and diarrhea. Both GLP-1 RAs and DPP-4 inhibitors are associated with pancreatitis.

Sodium-glucose cotransporter 2 (SGLT2) blocks glucose reabsorption in renal tubules, increasing glycosuria and leading to a reduction in plasma glucose levels and possibly weight loss.

Canagliflozin is the first such agent available in the United States. Side effects include an increased risk for urinary tract infection and vaginal and penile fungal infections. SGLT-2 inhibitors can also cause dehydration, electrolyte disturbances, and an increase in serum creatinine levels.

Bromocriptine (a dopamine-2 agonist) and colesevelam (a bile acid sequestrant) are both approved for the treatment of T2DM, but cause only mild reductions in A1c and are not widely used.

Insulin remains the therapy for patients with T1DM and patients with T2DM for whom oral agents do not achieve adequate glycemic control. The amylin analog pramlintide is an adjunctive therapy for patients with T1DM and insulin-treated T2DM.

ABNORMALITIES CAUSED BY HYPERGLYCEMIA

Acute hyperglycemia, even when not associated with DKA or the hyperglycemic hyperosmolar syndrome (HHS) is harmful for a number of reasons. If the blood glucose level exceeds the renal threshold for glucose (>240 mg/dL in a healthy person, but diminished with advancing age, renal insufficiency, and pregnancy), an osmotic diuresis ensues, with loss of glucose, electrolytes, and water. Hyperglycemia impairs leukocyte function through a variety of mechanisms. Patients with diabetes have an increased rate of wound infection, and hyperglycemia may also independently impair wound healing.

Chronic hyperglycemia is associated with an increased risk for the development of the microvascular and neuropathic complications of diabetes, as elegantly demonstrated in the Diabetes Control and Complications Trial (DCCT) for T1DM (10) and the United Kingdom Prospective Diabetes Study (UKPDS) for T2DM (11). In the DCCT, intensive therapy designed to maintain normal blood glucose levels greatly reduced the development and progression of retinopathy, microalbuminuria, proteinuria, and neuropathy as assessed over a 7-year period. Intensive therapy was not associated with increased mortality or major macrovascular events and did not decrease the quality of life, although it did increase the likelihood of severe hypoglycemic episodes. In addition, when patients enrolled in the

DCCT were followed over the next 12 years in the Epidemiology of Diabetes Interventions and Complications study, there was a significant reduction in rates of cardiovascular disease in those who had been intensely treated (12). In the UKPDS, aggressive treatment of blood glucose levels and hypertension was shown to decrease the risk of microvascular complications in patients with T2DM.

More recent studies, however, such as ACCORD, ADVANCE, and VADT have shown that in older patients with more advanced type 2 diabetes further intensifying control might cause harm (6). In the ACCORD trial those in the intensively treated group (target A1c of less than 6%) had an increased rate of mortality compared to those in the control group. The reasons for this increase in mortality is not well understood, but in all trials, in both intensive and control arms, episodes of severe hypoglycemia were associated with an increased risk for poorer outcomes, including death. Therefore, current guidelines suggest individualizing targets with a particular focus on decreasing the risk of severe hypoglycemia (6,7).

Among patients with known diabetes that is poorly controlled, there is no absolute level of blood glucose elevation that necessitates admission to the hospital or the administration of insulin. Admission is appropriate for the following:

1. *DKA* (see Chapter 205). Plasma glucose >250 mg/dL (>13.9 mmol/L) with (a) arterial pH <7.30 and serum bicarbonate level <15 mEq/L and (b) moderate ketonuria or ketonemia. DKA can occur in patients with normal blood glucose levels, particularly if they are vomiting frequently. Therefore, any blood sugar level in the setting of ketoacidosis can be indicative of DKA, even though an elevated blood sugar level is most common.
2. *HHS* (see Chapter 205). Impaired mental status and elevated plasma osmolality in a patient with hyperglycemia. This usually includes severe hyperglycemia (e.g., plasma glucose >600 mg/dL [>33.3 mmol/L]) and elevated serum osmolality (e.g., >320 mOsm/kg [>320 mmol/kg]).
3. Hypoglycemia (see Chapter 206). Only those patients with prolonged, severe or recurrent hypoglycemia require

hospitalization.

4. Severely symptomatic patient. Patients with T1DM who cannot tolerate oral fluids require hospitalization. Likewise, if the patient is severely symptomatic or the precipitating cause of hyperglycemia cannot be adequately treated in the ED, the patient needs to be admitted.

Generally, lowering the blood glucose level acutely in the ED in individuals without DKA or HHS has little benefit. It does not correct the underlying cause of hyperglycemia and has no long-term impact on the patient's blood glucose levels. Therefore, a plan must be formulated as to how the patient's blood glucose level will be lowered over time and how glycemic control will be maintained. The adequacy of follow-up is an extremely important consideration. Whether to give insulin in the ED is of lesser consequence and can be decided on an individual basis.

ED MANAGEMENT

New-Onset Diabetes

Most patients with diabetes have T2DM, and most of those are asymptomatic at diagnosis. The initial treatment for patients with newly discovered, asymptomatic diabetes is a trial of medical nutrition therapy (MNT; diet therapy) along with initiation of metformin therapy. Therefore, if an asymptomatic patient is noted incidentally to have an elevated blood glucose level in the ED, this can be followed up by the patient's outpatient physician. Patients who have mild-to-moderate symptoms of poorly controlled diabetes but have not previously been diagnosed can usually be treated on an outpatient basis, often with the initiation of low-dose oral antidiabetic agent therapy.

Controversy exists over the management of markedly symptomatic patients with newly discovered T2DM and blood glucose levels over 400 mg/dL. If close follow-up can be arranged, these patients can be started on maximal doses of a sulfonylurea agent and treated as outpatients. Generally, the patient feels better within 1 to 2 days, and, within a week, the blood glucose levels are markedly lower

(13). Their sulfonylurea dose can be tapered as they comply with MNT and metformin is added. In some, diabetes can be controlled with diet alone. However, patients who cannot drink adequate amounts of fluid, who have serious coexisting medical conditions (e.g., MI or systemic infection), or who do not have reliable follow-up should generally be hospitalized for initiation of therapy.

Patients with new-onset T1DM need to be started on lifelong insulin therapy. Many present with DKA. An occasional patient with new-onset T1DM who presents with mild manifestations and is judged to be very compliant can be started on insulin as an outpatient. T1DM patients begun on insulin as outpatients require basic education on insulin administration, self-monitoring of blood glucose, and close follow-up. Patients should be seen as soon as possible to receive thorough diabetes and nutrition self-management education.

MANAGEMENT OF HYPERGLYCEMIA DURING MEDICAL ILLNESS AND SURGERY

Serious medical illness and surgery produce a state of increased insulin resistance and relative insulin deficiency. Hyperglycemia can occur, even in nondiabetic patients, because of stress-induced insulin resistance plus the administration of dextrose-containing intravenous fluids. Increases of glucagon, catecholamines, cortisol, and growth hormone antagonize the effects of insulin, and insulin secretion is itself inhibited by the α-adrenergic effect of increased catecholamine levels. The counter-regulatory hormones also directly increase hepatic gluconeogenesis.

Although it was previously thought that inpatients did better with tighter glycemic control more recent data refutes this concept. Thus, inpatient target blood sugar levels are 140 to 180 mg/dL (14). When managing patients in the hospital with pre-existing diabetes, it is necessary to modify treatment regimens to compensate for both decreased caloric intake and increased physiologic stress.

It is strongly recommended that continuous intravenous infusions of dextrose and insulin be used in patients who are undergoing general anesthesia or are critically ill. Crucial to prevent ketosis in

patients with T1DM, this technique probably benefits patients with T2DM as well. Blood glucose levels must be measured with a glucose meter every hour, and the rates of insulin and dextrose infusion must be adjusted accordingly to prevent hypoglycemia or persistent hyperglycemia. Algorithms are available for insulin infusions, and the use of preprinted orders facilitates drug administration and reduces dosing errors.

- Frequent blood glucose monitoring is not always possible nor necessary for every patient, and patients with less serious illness or those undergoing minor surgery may do just as well with subcutaneously injected insulin. *A basal bolus insulin regimen rather than sliding-scale regular insulin should be used in these patients* (14). In patients going to surgery who have not received their dose of long/intermediate acting insulin for the day, giving 50% to 80% of the daily dose prior to surgery is often effective. At the same time, an intravenous infusion containing 5% dextrose should be started at a rate of 125 mL/hr. Blood glucose levels should be checked every 2 hours during surgery, and small doses of regular or rapid-acting insulin (lispro [Humalog], aspart [NovoLog], or glulisine [Apidra]) insulin should be given if values are >150 mg/dL.

The same principles of providing a constant source of insulin and carbohydrate apply to patients with T1DM who are not going to surgery but who must remain NPO owing to medical reasons. Patients should receive an injection of basal insulin (either glargine [Lantus] or detemir [Levemir]), with additional correction doses using regular insulin or a rapid-acting insulin (e.g., lispro), based on blood glucose levels. To avoid hypoglycemia, regular insulin should not be given more often than every 3 to 4 hours because a dose is effective for up to 6 hours. Rapid-acting insulins may be given every 3 hours. Once the patient is eating, a preprandial insulin dose can be added.

Patients with T2DM who are on insulin can follow similar guidelines. However, because patients with T2DM secrete some endogenous insulin and do not tend to develop ketosis, they can often be managed for brief periods without either insulin or dextrose.

However, if the blood glucose is <100 mg/dL, or >180 mg/dL, appropriate treatment is required.

Patients who have been taking an oral insulin secretagogue (such as a sulfonylurea agent or meglitinide) should have their blood glucose levels monitored when oral intake is not allowed, and intravenous dextrose with or without insulin should be given to keep blood glucose levels between 140 and 180 mg/dL. Metformin should not be given to hospitalized patients until it is clear that their renal function is stable. In general, for the initially hospitalized patients, oral antidiabetic medication should be held and then restarted once the patient is less acutely ill. The exceptions are DPP-4 inhibitors, which can be used in the hospital setting, with dose adjustments as needed based on renal function.

The emergency physician caring for the patient with diabetes who requires emergent surgery must notify the surgeon and the anesthesiologist of the patient's condition, obtain medical consultation when appropriate, and promptly initiate a thorough medical evaluation so as not to delay surgery.

Infections

Infections cause considerable morbidity and mortality among patients with diabetes. Infections may precipitate metabolic derangements and, conversely, the metabolic derangements of diabetes may facilitate infection. Depending on the population studied, infections have been identified as the precipitant in 26% to 77% of cases of DKA. A few infections, such as malignant otitis externa, rhinocerebral mucormycosis, and emphysematous pyelonephritis, occur almost exclusively in patients with diabetes. Certain infections, such as staphylococcal sepsis, occur more frequently and result in greater mortality among patients with diabetes, whereas others, such as pneumococcal pneumonia, affect diabetic patients no differently than the general population.

Although diabetes can compromise all aspects of host defenses against infection, all diabetic patients are nevertheless not equally susceptible to infection. Impairments in humoral immunity and polymorphonuclear leukocyte and lymphocyte function are

exacerbated by hyperglycemia and acidemia but are substantially, if not entirely, reversed by normalization of pH and blood glucose levels. Although the exact level above which impaired leukocyte function occurs has not been well defined, in vitro evidence suggests that glucose levels above 200 mg/dL impair leukocyte function (15).

Patients with long-standing diabetes also tend to develop microvascular and macrovascular disease, with resulting poor tissue perfusion and an increased risk of infection. The ability of skin to act as a barrier to infection may also be compromised when the diminished sensation of diabetic neuropathy results in unnoticed injury.

Ear, Nose, and Throat Infections

Two head and neck infections that are associated with high morbidity and mortality—malignant otitis externa and rhinocerebral mucormycosis—are seen almost exclusively in diabetic patients.

Malignant or necrotizing otitis externa principally occurs in older patients with diabetes and is almost always caused by *Pseudomonas aeruginosa*. The infection starts in the external auditory canal and spreads to the adjacent soft tissue, cartilage, and bone. Patients typically present with severe ear pain and otorrhea and, although they often have a pre-existing otitis externa, the progression to invasive disease is usually rapid. Examination of the auditory canal may reveal granulation tissue, but spread of infection to the pinna, the preauricular tissue, and the mastoid often makes the diagnosis apparent. Involvement of cranial nerves, particularly the facial nerve, is common; when there is extension to the meninges, the outcome is often fatal. Computed tomography (CT) is useful to define the extent of disease.

Prompt surgical consultation is mandatory for malignant otitis externa, because surgical debridement is often an essential part of therapy. Intravenous antipseudomonal antibiotic therapy should be started at once in patients with invasive disease. Diabetic patients with severe otitis externa but no evidence of invasive disease can be treated with an otic antibiotic drop and oral ciprofloxacin, but they require close follow-up.

Mucormycosis is the name given collectively to the infections caused by various ubiquitous molds (16). Invasive disease occurs in poorly controlled diabetic patients, especially in conjunction with DKA although it can occur in individuals with type 2 diabetes, as well. In these patients, the organism colonizes the nose and paranasal sinuses, spreading into adjacent tissues by invading blood vessels and causing soft tissue necrosis and bony erosion. Patients usually present with periorbital or perinasal pain and various degrees of swelling and induration. There may be a bloody nasal discharge. Involvement of the orbits, with eyelid swelling, proptosis, and diplopia, is common. The nasal turbinates may appear dusky red or frankly necrotic. The appearance of black necrotic tissue is an important visual clue. As the illness progresses, there is invasion of the cranial vault through the cribriform plate, which may result in cerebral abscess, cavernous sinus thrombosis, or internal carotid artery thrombosis. Wet smears of the necrotic tissue often reveal broad hyphae and distinguish mucormycosis from a severe facial cellulitis.

CT helps to delineate the extent of disease. Treatment consists of control of the predisposing hyperglycemia and acidemia, intravenous amphotericin B, and immediate surgical debridement. Until the diagnosis is confirmed, treatment with antistaphylococcal antibiotics is appropriate.

Urinary Tract Infection

Patients with diabetes have a 60% increased risk of urinary tract infection compared to individuals without diabetes (17). More importantly, people with diabetes are increased risk for serious upper urinary tract infection. Intrarenal bacterial infection should be considered in the differential diagnosis of any patient with diabetes who presents with flank or abdominal pain.

The treatment of cystitis is essentially the same as in nondiabetic patients, although individuals with a neurogenic bladder due to diabetic neuropathy may not empty the bladder well and may require urologic referral. Sulfonamide antibiotics can cause hypoglycemia among patients taking sulfonylurea agents by

displacing the sulfonylurea agents from their binding sites and increasing their hypoglycemic effect.

The principles of treatment of pyelonephritis do not differ for diabetic patients, but a lower threshold for hospital admission is appropriate for at least two reasons. First, pyelonephritis makes control of diabetes more difficult by causing insulin resistance; in addition, nausea may limit the patient's ability to maintain normal hydration. The ensuing hyperglycemia further compromises the immune response. Second, diabetic patients are more susceptible to the complications of pyelonephritis, including renal abscess, emphysematous pyelonephritis, renal papillary necrosis, and gram-negative sepsis.

Emphysematous pyelonephritis can occur in patients with diabetes (18). This is an uncommon necrotizing infection of the kidney caused by *Escherichia coli, Klebsiella pneumoniae,* or other organisms capable of fermenting glucose to carbon dioxide. The presentation is usually similar to that of uncomplicated pyelonephritis. The diagnosis is established by identifying renal gas on plain radiography, ultrasonography, or noncontrast helical CT urography. Management consists of intravenous antibiotics and supportive care plus percutaneous drainage or emergency nephrectomy in more severe cases.

Skin and Soft Tissue Infections

Sensory neuropathy, atherosclerotic vascular disease, and hyperglycemia all predispose diabetic patients to skin and soft tissue infections. These can affect any skin surface but most commonly involve the feet. Even the smallest wound can be complicated by cellulitis, lymphangitis and, more ominously, staphylococcal sepsis. Minor wound infections and cellulitis are typically caused by *Staphylococcus aureus* or hemolytic streptococci and generally can be treated with a penicillinase-resistant synthetic penicillin or a first-generation cephalosporin. Diabetes, however, is a risk factor for the development of MRSA infections. Severe skin and soft tissue infections, and even minor purulent infections, should be treated with an antibiotic effective against MRSA, such as vancomycin for

serious infections, and clindamycin or cephalexin plus trimethoprim-sulfamethoxazole for less severe infections.

Outpatient treatment of minor infections is appropriate if the patient is reliable, performs self-monitoring of blood glucose levels (and urine ketones for T1DM patients), and has close follow-up available. Wounds and, in particular, cutaneous ulcers can also be complicated by necrotizing infections of the skin, subcutaneous tissues, fascia, or muscle. These infections are typically polymicrobial, involving group A streptococci, enterococci, *S. aureus,* Enterobacteriaceae, and various anaerobes. Radiographs should be taken of any spreading soft tissue infection in a diabetic patient to look for the soft tissue gas that characterizes these infections. Surgical debridement is necessary for necrotizing infections. Gram stains and surface cultures are not helpful; antibiotic coverage should reflect the range of potential pathogens.

Osteomyelitis

Contiguous spread of a polymicrobial infection from a skin ulcer to adjacent bone is common in diabetic patients. In one study, osteomyelitis was found underlying 68% of diabetic foot ulcers, and physical examination and plain radiographs each failed to make the diagnosis in one-half of patients. The consensus guidelines for diagnosing osteomyelitis recommend an aseptically obtained bone sample with histopathologic findings of inflammation and microorganisms found on culture (17). Other diagnostic tests for osteomyelitis are probing to bone, the erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), sequential x-rays, and MRI. CT and nuclear medicine scans and are less helpful.

In the ED, where physical examination, ESR, and plain radiographs are the commonly employed diagnostic modalities, the diagnosis is more frequently suspected than definitively established. If osteomyelitis is apparent by radiograph or physical examination (e.g., if wounds are deep enough to expose tendons or bone, or probes to the bone), the patient should be admitted for intravenous antibiotics. If osteomyelitis is suspected but admission is not

necessitated by the soft tissue infection or metabolic disturbances, the patient can be discharged to have an outpatient workup.

Other Infections

Although cholecystitis is probably no more common in patients with diabetes than in the general population, severe fulminating infection, especially with gas-forming organisms, is. The early clinical manifestations of emphysematous cholecystitis are indistinguishable from those of usual cholecystitis. The diagnosis can be made by finding gas in the gallbladder lumen, wall, or surrounding tissues. Even with immediate surgery, mortality is high. Clostridial species are found in more than 50% of cases.

Diabetic patients have a greater incidence of staphylococcal and *Klebsiella* pneumonia than do persons without diabetes. Diabetes is also a risk factor for reactivation of tuberculosis. Cryptococcal infections and coccidioidomycoses are more virulent in diabetic patients.

Ophthalmologic Abnormalities

Visual complaints by diabetic patients should be taken very seriously. Diabetes can affect the lens, the vitreous, and the retina, causing visual symptoms that may prompt the patient to come to the ED. Visual blurring may develop acutely as the lens changes shape with marked changes in blood glucose concentrations. This effect, which is caused by osmotic fluxes of water into and out of the lens as the blood glucose concentration varies, usually occurs as hyperglycemia increases, but it may also be seen when high blood glucose levels are lowered rapidly. In either case, recovery to baseline visual acuity can take up to a month, and some patients are almost completely unable to read small print or do close-up work during this period.

Rarely, patients with T1DM who are in extremely poor control (e.g., those with frequent episodes of DKA) can acutely develop a “snowflake” (or “metabolic”) cataract. Named for their snowflake or flocculent appearance, these cataracts can progress rapidly and

create total opacification of the lens within a few days. Surgery is often required to restore vision. Patients with diabetes also tend to develop senile cataracts at a younger age than do persons without diabetes, although not in relation to the degree of glycemic control.

Diabetic retinopathy remains the leading cause of blindness among persons aged 20 to 64 in the United States (19). Some degree of diabetic retinopathy can be expected to develop in nearly all patients with TIDM and approximately 60% of patients with T2DM who have had the disease for 20 years or more. Patients with T2DM may already have diabetic retinopathy at the time their diabetes is diagnosed.

There are five stages in the progression of diabetic retinopathy:

1. Dilation of the retinal venules and formation of retinal capillary microaneurysms
2. Increased vascular permeability
3. Vascular occlusion and retinal ischemia
4. Proliferation of new blood vessels on the surface of the retina
5. Hemorrhage and contraction of the fibrovascular proliferation and the vitreous

The first two stages of diabetic retinopathy are known as “background” or nonproliferative retinopathy. Initially, the retinal venules dilate, then microaneurysms, which appear as tiny red dots on the retina and cause no visual impairment, develop. As the microaneurysms or retinal capillaries become more permeable, hard exudates appear, reflecting the leakage of plasma. These are sharply defined yellow deposits composed mostly of lipid material. Rupture of intraretinal capillaries results in hemorrhage. If these ruptures occur deep in the retina, they appear as “dot blot” hemorrhages that can be difficult to distinguish from microaneurysms. If a more superficial capillary ruptures, a flame-shaped hemorrhage appears. Hard exudates are often found in partial or complete rings (circinate pattern), which usually include multiple microaneurysms. These rings usually mark an area of edematous retina.

No change in visual acuity may be noted by the patient, unless the center of the macula is involved. Macular edema can cause visual loss, however, so it is extremely important to refer patients with

suspected macular edema to an ophthalmologist for evaluation and possible laser therapy. Laser therapy is effective in decreasing macular edema and preserving vision, but it is less effective in restoring vision once it is lost. The advent of intravitreal anti-vascular endothelial growth factor (anti-VEGF) therapy has added a new dimension to the treatment of diabetic retinopathy, particularly macular edema where it is considered by many to be first-line therapy (20).

Preproliferative and proliferative diabetic retinopathy are the next stages in the progression of the disease. Cotton-wool spots can be seen in preproliferative retinopathy. These represent retinal microinfarcts owing to capillary occlusion and are off-white to gray patches with poorly defined margins.

Proliferative retinopathy is characterized by neovascularization, the development of networks of fragile new vessels that are often seen on the optic disc or along the main vascular arcades. The vessels undergo cycles of proliferation and regression. During proliferation, fibrous adhesions develop between the vessels and the vitreous. Subsequent contraction of the adhesions can result in traction on the retina and retinal detachment. Contraction also tears the fragile new vessels, which hemorrhage into the vitreous. Patients with T2DM do not develop proliferative retinopathy as often as those with T1DM.

Often, the first hemorrhage is small and is noted by the patient as a fleeting, dark area, or “floater,” in the field of vision. Because subsequent hemorrhages can be larger and more serious, the patient should be referred immediately to an ophthalmologist for laser therapy anti-VEGF treatment, or both. Patients with retinal hemorrhage should be advised to limit their activity and keep their head upright (even while sleeping), so that the blood settles to the inferior portion of the retina, thus obscuring less central vision.

Patients with active proliferative diabetic retinopathy are at increased risk for retinal hemorrhage if they receive thrombolytic therapy, so this condition is a relative contraindication to the use of thrombolytic agents.

Diabetic Nephropathy

Diabetes is the leading single cause of end-stage renal failure in the United States. Although the prevalence of diabetic nephropathy varies with the duration of diabetes and can be substantially reduced by improved glycemic and hypertension management, all patients with diabetes should be considered to have the potential for renal impairment unless proven otherwise. Potentially nephrotoxic drugs should be avoided whenever possible. Renally excreted or potentially nephrotoxic drugs should be given at reduced dosage as appropriate to the patient's serum creatinine level, creatinine clearance, or estimated glomerular filtration rate (eGFR).

The use of contrast media, including ionic and nonionic contrast can cause reductions in renal function, and precipitate acute renal failure in patients with underlying diabetic nephropathy. While most patients recover within 10 days, some develop irreversible renal failure. Caution should be used when contrast-enhanced studies are being considered in patients with diabetes with an eGFR) <60 mL/min or a serum creatinine level ≤ 1.5 mg/dL. In general an ultrasound or a noncontrast study should be performed.

Patients with diabetes who must undergo contrast medium–enhanced studies should be well hydrated before, during, and after the procedure and should have careful monitoring of renal function. Data are mixed both with regard to the use of isotonic saline versus a sodium bicarbonate containing fluid for hydration, and the utility of oral N-acetylcysteine to reduce nephrotoxicity (21). The appropriate selection of contrast agents may also reduce nephrotoxicity. Iso-osmolar iodixanol or a nonionic low osmolal agent (e.g., iopamidol or ioversol) are preferable to iohexol (22).

In contrast, the administration of gadolinium-containing contrast agents used in MRI scanning are of concern only in patients with chronic kidney disease (CKD), in whom there is a risk of a serious adverse reaction termed nephrogenic systemic fibrosis. Since many patients with long-standing diabetes have CKD, caution is warranted in those in whom gadolinium contrast is being considered. Because chronic blood pressure elevation contributes to the decline in renal function, it is extremely important that patients with diabetes who are found to be hypertensive be referred for chronic blood pressure

management. If antihypertensive therapy is to be started in the ED, an angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB) is a good choice because these agents have been found to reduce the rate of decline in renal function, independent of their effect on blood pressure. They also decrease proteinuria among patients with diabetic nephropathy. It should be kept in mind, however, that ACE inhibitors and ARBs tend to increase the serum potassium level and should thus be used with caution in patients with renal insufficiency or somewhat elevated serum potassium levels.

Diabetic Neuropathy

Diabetic neuropathy is common, and distal symmetric sensorimotor polyneuropathy (in a "glove-and-stocking" distribution) is the most frequent pattern. In addition to the pain often experienced in its early stages, this type of neuropathy eventually leads to loss of sensation. The combination of decreased sensation and peripheral arterial insufficiency often leads to foot ulceration and eventual amputation.

A variety of acute-onset neuropathies occur in diabetic patients, including acute cranial mononeuropathies, mononeuropathy multiplex, focal lesions of the brachial or lumbosacral plexus, and radiculopathies. Of the cranial neuropathies, third oculomotor nerve palsy is the most common, followed by sixth (abducens) and fourth (trochlear) nerve palsies. Patients can present with diplopia and eye pain. In diabetic third-nerve palsy, the pupil is usually spared, whereas in third-nerve palsy owing to intracranial aneurysm or tumor, the pupil is affected in 80% to 90% of cases. It is important to consider nondiabetic causes for cranial nerve palsies, including intracranial tumors, aneurysms, and brainstem stroke (23). Evaluation should, therefore, include either nonenhanced and contrast medium–enhanced CT or, preferably magnetic resonance imaging. Neurologic consultation is recommended. Acute cranial nerve mononeuropathies usually resolve within 2 to 9 months. Acute thrombosis of the blood vessels supplying the nerve involved is thought to be the cause.

Autonomic dysfunction can involve any part of the sympathetic or parasympathetic chains and produce myriad manifestations (24). Patients likely to seek care in the ED include those with diabetic gastroparesis and vomiting, severe diarrhea, bladder dysfunction and urinary retention, and symptomatic orthostatic hypotension. Symptoms tend to wax and wane over time. Treatment is only symptomatic. Patients with gastroparesis may benefit from the use of metoclopramide or erythromycin. Before these therapies are started, the degree of dehydration and metabolic imbalance must be assessed, and other serious causes of vomiting must be excluded. In severe cases, gastric pacing has been used. Patients with disabling orthostatic hypotension may be treated with salt tablets, support stockings, or fludrocortisone. Alleviating the functional abnormalities associated with the autonomic neuropathy is often difficult and frustrating for both doctor and patient. The patient's primary physician, and often an appropriate subspecialist, should be involved in devising a long-term treatment plan.

The Diabetic Foot

Fifty percent to 70% of all nontraumatic lower-extremity amputations occur in patients with diabetes (25). The insensate, poorly perfused foot is at risk for ulcers from pressure necrosis or inflammation from repeated skin stress and unnoticed minor trauma. Either can evolve into cellulitis, osteomyelitis, or nonclostridial gangrene and end in amputation.

Wounds, infections, or ulcers of the feet demand particular attention in the diabetic patient. In addition to appropriate use of antibiotics, it is mandatory to avoid further trauma to the healing foot through use of crutches, a wheelchair, or bed rest. If bone or tendon is visible, osteomyelitis is present, and hospitalization for intravenous antibiotics is often necessary. Many patients need a vascular evaluation in conjunction with local treatment of the foot ulcer, because, in some cases, a revascularization procedure may be required to provide adequate blood flow for wound healing. For patients who may be discharged, every attempt should be made to ensure frequent follow-up, optimally with a podiatrist or an

orthopedist with experience in the care of a diabetic foot. If such follow-up is not available, hospitalization may be necessary for initial treatment.

Because curing ulcers and foot infections is difficult, their prevention is extremely important. At one clinic, the rate of amputation was halved after patients were required to remove their shoes and socks at every visit. The emergency physician can contribute to prevention by briefly inspecting the feet of each patient with diabetes and by educating them about the need for proper foot care and maintenance of near-normal blood sugar levels. Patients who have a loss of sensation and/or structural abnormalities, who smoke, or have a history of prior lower-extremity complications should be referred to a foot care specialist for ongoing preventive care and lifelong surveillance.

Macrovascular Complications

Macrovascular disease is the leading cause of death in patients with diabetes. It is responsible for approximately 65% to 75% of deaths in patients with diabetes, compared with approximately 35% of deaths in the general population. Subtle differences in the pathophysiology of atherosclerosis in patients with diabetes result in both earlier development and a more malignant course. The presence of diabetes causes a twofold increase in MI in men and a fourfold increase in women. The risk of stroke is doubled, and the risk of developing peripheral vascular disease is increased fourfold. In fact, it has been shown that patients with T2DM who have never had an MI have the same risk of having an MI as patients without diabetes who have had a prior MI.

Patients with diabetes may have an increased incidence of silent ischemia. However, silent ischemia is common in many patients with CAD, and the apparently increased incidence may be because patients with diabetes are more likely than others to have CAD to begin with. Nevertheless, electrocardiography is prudent in patients with diabetes and a serious illness or who present with generalized weakness, malaise, or other nonspecific symptoms that are not expected to be due to myocardial ischemia.

Hypertension, which also increases the risk of atherosclerosis, is twice as common among patients with T2DM. Because of their high-risk profile, most patients with type 2 diabetes should be taking a daily aspirin (81 mg to start), an HMG-CoA-reductase inhibitor (statin), and an ACE inhibitor or an ARB agent. Aggressive global risk reduction, reinforced by all health care providers, is needed to lower the morbidity and mortality associated with diabetes.

CRITICAL INTERVENTIONS

- Maintain the blood glucose levels of patients with wounds or active infections <180 mg/dL.
- Provide adequate hydration to patients with mild diabetic nephropathy before contrast material is given to avoid precipitating acute renal failure.

Common Pitfalls

- Failure to provide patients who have T1DM with a continuous source of insulin and glucose when they are unable to tolerate oral intake.
- Underestimating the severity of diabetic retinopathy on funduscopic examination through undilated pupils. Any patient with lesions near the macula should be referred urgently to an ophthalmologist.
- Failure to examine the feet; overlooking small ulcers or underestimating their seriousness.
- Failure to consider myocardial ischemia in patients with nonspecific symptoms.

CHAPTER 205

Hyperglycemic Crises

Scott R. Votey and Anne L. Peters

Diabetic ketoacidosis (DKA) is the syndrome defined by the biochemical presence of hyperglycemia, ketonemia, and acidemia. Hyperosmolar hyperglycemic state (HHS) is a closely related disorder in which hyperglycemia occurs in the absence of significant ketonemia and acidemia. HHS and DKA are often collectively referred to as **hyperglycemic crises**. The underlying cause of both conditions is insulin deficiency and concomitant elevation of counterregulatory hormones, and the two syndromes represent different points along a single biochemical and clinical spectrum although DKA occurs primarily, but not exclusively, in people with type 1 diabetes and HHS mostly in people with type 2 diabetes. The American Diabetes Association (ADA) diagnostic criteria are useful in establishing the diagnosis of DKA and distinguishing it from HHS (Table 205.1) (1). Individual patients may present with DKA and HHS at different times, and a single episode may have features of both syndromes. However, there are important differences in the management of DKA and HHS.

TABLE 205.1
Diagnostic Criteria for Diabetic Ketoacidosis and Hyperosmolar Hyperglycemic State

Diagnostic Criteria and Classification	DKA			HHS
	Mild	Moderate	Severe	
Plasma glucose (mg/dL)	>250	>250	>250	>600
Arterial pH	7.25–7.30	7.00 to <7.25	<7.00	>7.30
Serum bicarbonate (mEq/L)	15–18	10 to <15	<10	>15
Urine ketone[a]	1–3+	3–4+	3–4+	Trace to 1+
Serum ketone[a]	Positive	Positive	Positive	Small
Effective serum osmolality[b]	Variable	Variable	Variable	>320 mOsm/kg
Anion gap[c]	>10	>12	>12	<12
Mental status	Alert	Alert/drowsy	Stupor/coma	Stupor/coma

[a]Nitroprusside reaction method.
[b]Calculation of effective serum osmolality: 2[measured Na^+ (mEq/L)] + [glucose (mg/dL)]/18.
[c]Calculation of anion gap: (Na^+) – [Cl^- + HCO_3^- (mEq/L)].
DKA, diabetic ketoacidosis; HHS, hyperosmolar hyperglycemic state.
Modified from Kitabchi AE, Umpierrez GE, Miles JM, et al. Hyperglycemic crises in adult patients with diabetes. *Diabetes Care*. 2009;32(7): 1335–1343.

DKA affects 0.5% to 0.8% of patients with diabetes annually, resulting in approximately 140,000 hospitalizations per year in the United States or 4% to 9% of diabetes admissions (2). Hospitalizations for DKA are increasing, and the estimated annual cost has risen to $2.4 billion (1). DKA encompasses a spectrum of severity from minimally symptomatic to critically ill and can be graded as mild, moderate, and severe (1). This grading facilitates the tailoring of evaluation and management to the needs of the individual patient.

Although the majority of DKA cases occur in patients with type 1 diabetes mellitus, it is increasingly recognized as a complication of type 2 diabetes, particularly in the setting of new-onset diabetes among obese African American and Hispanic young adults, teens, and children (3). DKA is more common in adults (approximately 80% of cases) than children, with 37% of patients older than 50 years (4).

Although the per-episode mortality in published series has declined since 1980, it remains significant at approximately 1% (5). Mortality is higher in persons >65 years of age and in the presence of major chronic comorbidities, such as end-stage renal disease, or acute comorbidities, such as myocardial infarction or sepsis (1).

HHS has been known by several other names in the past, including hyperosmolar nonketotic state and hyperosmolar coma. HHS is the

term currently endorsed by the ADA because it more accurately reflects the clinical and biochemical features of the illness; specifically, mild ketosis is common in HHS, and coma is present in only $<30\%$ of cases (6,7).

HHS is primarily a complication of type 2 diabetes but may also occur in type 1 diabetes. Thirty percent to 40% of episodes occur in the absence of a prior history of diabetes, although most previously undiagnosed patients will prove to have mild type 2 diabetes. HHS is less common than DKA and accounts for $<1\%$ of diabetes admissions (7). The mean age of patients suffering HHS has been approximately 65 years, but the incidence is increasing in young adults, adolescents, and children as the prevalence of type 2 diabetes increases in these age groups.

The mortality rate of HHS is 5% to 20% (1), substantially higher than that of DKA. Patients with major acute or chronic comorbidities and more severe illness on presentation as indicated by coma, hypothermia, or hypotension have higher mortality rates (6,7); older age and higher osmolality have been associated with increased mortality in some (8) but not all series.

CLINICAL PRESENTATION

The clinical presentation, diagnostic evaluation, and management of the hyperglycemic crises can be best understood through an appreciation of the pathophysiology. DKA and HHS occur as a result of insufficient effective circulating insulin. In healthy individuals, glucose homeostasis is maintained by a balance between circulating insulin levels and the counterregulatory hormones: glucagon, catecholamines, cortisol, and growth hormone. Insulin acts to increase glucose utilization and to suppress gluconeogenesis, glycogenolysis, and ketogenesis. Without adequate insulin, glucose cannot be utilized as energy substrate. The counterregulatory hormones have the opposite effect, decreasing glucose uptake and utilization and promoting gluconeogenesis, lipolysis, and ketogenesis. The ketones acetoacetate and β-hydroxybutyrate can be used as substrate by the brain and other tissues but, in excess, cause ketonemia and metabolic acidosis. Insufficient insulin effect results

in an elevated blood glucose, ketonemia, and ketoacidemia. Functional insulin deficiency may result from the absence of insulin (absolute insulin deficiency) or elevated counterregulatory hormones that overwhelm insulin's effect in the presence of normal or even high circulating insulin levels (relative insulin deficiency). Episodes of DKA and HHS are typically the result of the simultaneous occurrence of both insufficient insulin and elevated counterregulatory hormones.

Hyperglycemic crises, including both DKA and HHS, are associated with high levels of circulating proinflammatory cytokines, oxidative stress and circulating adhesion molecules promoting platelet aggregation (9). These abnormalities may play a role in the cerebral edema seen in DKA, and the high rate of myocardial infarction and stroke seen in association with hyperglycemic crises in older patients. Treatment of hyperglycemic crises with insulin and normalization of the serum glucose corrects these abnormalities.

The biochemical abnormalities and clinical features of the hyperglycemic crises are the direct product of insulin deficiency (Fig. 205.1). Insulin deficiency results in gluconeogenesis, glycogenolysis, and decreased glucose utilization with resultant hyperglycemia. Hyperglycemia produces an osmotic diuresis that accounts for the polyuria and polydipsia seen early in the course of hyperglycemic crises and the dehydration with tachycardia and hypotension that develop later in the course. Water and electrolyte deficits are variable but are typically quite large (see Table 205.2).

TABLE 205.2
Typical Total Body Deficits in DKA and HHS

Typical Deficits	DKA	HHS
Total water (L)	6	9
Water (mL/kg)	100	100–200
Na^+ (mEq/kg)	7–10	5–13
Cl^- (mEq/kg)	3–5	5–15
K^+ (mEq/kg)	3–5	4–6
PO_4^- (mmol/kg)	5–7	3–7
Mg^{2+} (mEq/kg)	1–2	1–2
Ca^{2+} (mEq/kg)	1–2	1–2

DKA, diabetic ketoacidosis; HHS, hyperosmolar hyperglycemic state.

Diabetic Ketoacidosis

If insulin deficiency is more severe, ketogenesis accelerates and ketoacids are generated, resulting in DKA. Ketonemia gives rise to nausea, vomiting, and abdominal pain. If these symptoms inhibit fluid intake, dehydration worsens, urine output diminishes, and, in the absence of brisk osmotic diuresis, ketoacid and glucose levels climb and result in acidemia and hyperosmolarity, which in turn engender altered mentation. Respiratory alkalosis with tachypnea is the compensatory response to the ketoacidemia.

Inadequate insulin therapy (nonadherence or an insufficient regimen) resulting in absolute insulin deficiency is a common precipitant of DKA, especially in populations with low income, no health insurance, and low educational levels (Table 205.3) (10). Psychological issues, including eating disorders, are common factors in younger patients. Continuous subcutaneous insulin infusion devices (CSII, insulin pumps) have been associated with a higher incidence of DKA, but with technological improvements this may no longer be the case (11).

TABLE 205.3
Common Precipitants of Diabetic Ketoacidosis

Insufficient Insulin

- Nonadherence (~30%); low income, no health insurance, psychological issues, low educational attainment
- New-onset diabetes (~20%); in both type-1 and type-2 diabetes

Insulin Resistance

- Infection (pneumonia, urinary tract infection, sepsis) (~35%)
- Other medical illness (myocardial infarction, stroke, pancreatitis) and surgery (~15%)
- Medications; corticosteroids, sympathomimetics, second-generation (atypical) antipsychotics (clozapine, olanzapine, and others)

Major illness, most commonly infections but also myocardial infarction, stroke, pancreatitis, and other illnesses that provoke high levels of counterregulatory hormones and insulin resistance, are common precipitants of DKA. New-onset diabetes is identified in

approximately 20% of cases (1,7). Medications, including corticosteroids and second-generation antipsychotics (12), can precipitate DKA, even in patients without a history of diabetes.

DKA develops in hours or more commonly in days, with the onset more rapid in the presence of low circulating insulin levels and more severely elevated counterregulatory hormones, as occurs in the presence of major illness. The ability to consume fluids and maintain a high urine output and thereby an osmotic diuresis of glucose and ketoacids is an important compensatory mechanism as DKA develops. Conversely, the inability to consume fluids and the presence of impaired renal function, particularly anuric renal failure, accelerate the development and exacerbate the severity of DKA.

Polyuria, an early symptom, diminishes as the patient becomes dehydrated. Signs of dehydration (dry mucous membranes, poor skin turgor, tachycardia, positional dizziness, and hypotension) and catecholamine response (tachycardia) may be prominent. Patients typically progress from polydipsia to anorexia, nausea, and vomiting. Abdominal distention, diminished bowel sounds, and abdominal tenderness are present in 50% to 75% of DKA cases (13). Gastric distention and evidence of ileus may be seen on abdominal radiography. All of these abdominal abnormalities may be ascribed to ketosis, but if abdominal pain and tenderness are prominent or fail to improve as metabolic abnormalities resolve, other intra-abdominal pathology should be considered.

Ketoacidosis presents as hyperpnea (an increase in both the rate and depth of breathing) and with the odor of acetone on the breath. In the absence of severe hypotension, altered mentation—lethargy, confusion, or even coma—correlates with, and has been attributed to the severity of the hyperglycemia and hyperosmolarity (7) or the acidosis (14).

Symptoms of a precipitating illness may dominate the clinical presentation or may be obscured by the symptoms of the metabolic derangements of DKA. Signs and symptoms of infection should be sought. Fever is an unreliable sign of infection in patients with DKA and HHS. In fact, DKA and HHS patients presenting with

hypothermia often have a serious underlying infection, and hypothermia is associated with a higher mortality rate (1).

Hyperosmolar Hyperglycemic State

The essential pathophysiologic difference between DKA and HHS is in the severity of insulin deficiency (Fig. 205.1). Higher levels of effective circulating insulin are required to maintain glucose homeostasis than to suppress ketogenesis. HHS develops when circulating insulin levels are adequate to suppress ketogenesis but inadequate to promote glucose utilization or suppress gluconeogenesis. HHS is, therefore, primarily found in patients who secrete some insulin but have insulin resistance at baseline (and may have a diagnosis of type 2 diabetes) and are experiencing a concurrent illness that elevates counterregulatory hormones, exacerbating insulin resistance and resulting in hyperglycemia.

Even more than with DKA the clinical features of HHS are the result of hyperglycemia. Hyperglycemia produces an osmotic diuresis of glucose, which accounts for the polyuria and polydipsia seen early in the course of HHS and the physical signs of dehydration including dry oral mucosa, poor skin turgor, weight loss, generalized weakness, postural dizziness, tachycardia, and hypotension that develop later. HHS develops insidiously over several days to weeks in contrast to DKA, which commonly develops over hours to 1 to 2 days. Water and electrolyte losses are large and typically exceed those found in DKA (Table 205.2), presumably owing to the prolonged diuresis that results in a gradual decline and frequently a delayed diagnosis. Ingestion of fluids to replace fluids lost is an important compensatory mechanism as HHS develops. Impaired thirst, the inability to consume fluids, or a lack of access to fluids accelerates the development of HHS.

As net water and solute loss worsens, hyperosmolarity in the extracellular space promotes movement of water out of the intracellular space, resulting in intracellular hyperosmolarity and cellular dysfunction. Although this process occurs in all tissues, alterations in brain function dominate the clinical presentation and correlate with rising osmolarity. The most common reason patients

with HHS are brought to medical attention is a decreased level of responsiveness. Although there is substantial individual variation, confusion and lethargy are increasingly common as the effective osmolarity exceeds 320 mOsm/L, obtundation with an osmolarity of >340 mOsm/L, and coma with an osmolarity of >350 mOsm/L (7). Hyperosmolarity may also cause a variety of other neurologic signs and symptoms. Seizures, both focal and generalized, have been reported in 15% of cases (15). Focal weakness, aphasia, dysphagia, myoclonic jerks, and chorea may also occur. Neurologic findings may mimic an acute stroke, yet resolve with treatment of the HHS. Conversely, recrudescence of the signs of a prior stroke may occur during an episode of HHS, and an acute stroke may coexist with or precipitate HHS.

Nausea is common with HHS, but repeated vomiting and abdominal pain are less common with HHS than DKA, presumably because the ketosis is less severe. Prominent abdominal symptoms should prompt consideration of possible coexisting intra-abdominal pathology.

Major illnesses, most commonly infection but also myocardial infarction, stroke, pancreatitis, and other illnesses that provoke high levels of counterregulatory hormones and insulin resistance, are common precipitants of HHS (1). Pneumonia, urinary tract infection, and sepsis are the most common infections. Symptoms of a precipitating illness may dominate the clinical presentation, or may be difficult to discern due to altered mental status (AMS).

Medications such as corticosteroids, thiazide, and other diuretics and second-generation antipsychotics (particularly clozapine and olanzapine) can precipitate HHS (1). Reduced thirst and decreased water intake commonly contributes. Tube feedings and parenteral nutrition have also been implicated. Among patients with known diabetes, noncompliance with medications, failure to monitor blood glucose, and poor diabetes education can also contribute to the development of HHS.

DIFFERENTIAL DIAGNOSIS

There is significant overlap in the clinical and biochemical features of DKA and HHS. Depending on the criteria used and the population studied, one-third to one-half of patients have a mixed disorder with features of both conditions (6,16), either hyperosmolarity in patients who meet diagnostic criteria for DKA or mild ketoacidosis in patients whose presentation otherwise is consistent with HHS. The essential action is to exclude moderate-to-severe ketoacidosis in the setting of hyperglycemia. Patients with DKA tend to be younger, to have become ill more rapidly, and to demonstrate the signs and symptoms of ketoacidosis: nausea, vomiting, abdominal pain, rapid deep breathing, and an odor of acetone on the breath. The presence of 3 to 4+ ketonuria on urinalysis supports the diagnosis of DKA, so urinalysis should be performed early in the assessment. By definition, patients with HHS have a serum pH $\leq$7.3, a serum bicarbonate $>$18 mEq/L, and low levels of ketonemia and ketonuria. However, a mild anion gap metabolic acidosis is common in HHS, probably owing to the contributions of ketoacids, lactic acid, and renal insufficiency with accumulation of fixed acid metabolites. A venous or arterial blood gas (ABG) can exclude severe acidosis in the critically ill. The measurement of serum electrolytes and calculation of the anion gap is sufficient in less severely ill patients.

In addition to DKA, ketosis may result from any physiologic starvation state, including fasting, hyperemesis of pregnancy, and ketotic hypoglycemia. The causes of metabolic acidosis are numerous, including lactic acidosis and uremic acidosis (see Chapter 203). It is the simultaneous convergence of hyperglycemia, ketosis, and metabolic acidosis that establishes the diagnosis of DKA (Fig. 205.2). In the case of a patient known to have diabetes who presents with the typical signs and symptoms of the metabolic derangements of DKA, it is enough to establish the presence of hyperglycemia, ketosis, and acidosis to be confident of the diagnosis. In cases where the history is less definitive, particularly when there is a severe metabolic acidosis, it is important to consider alternative causes.

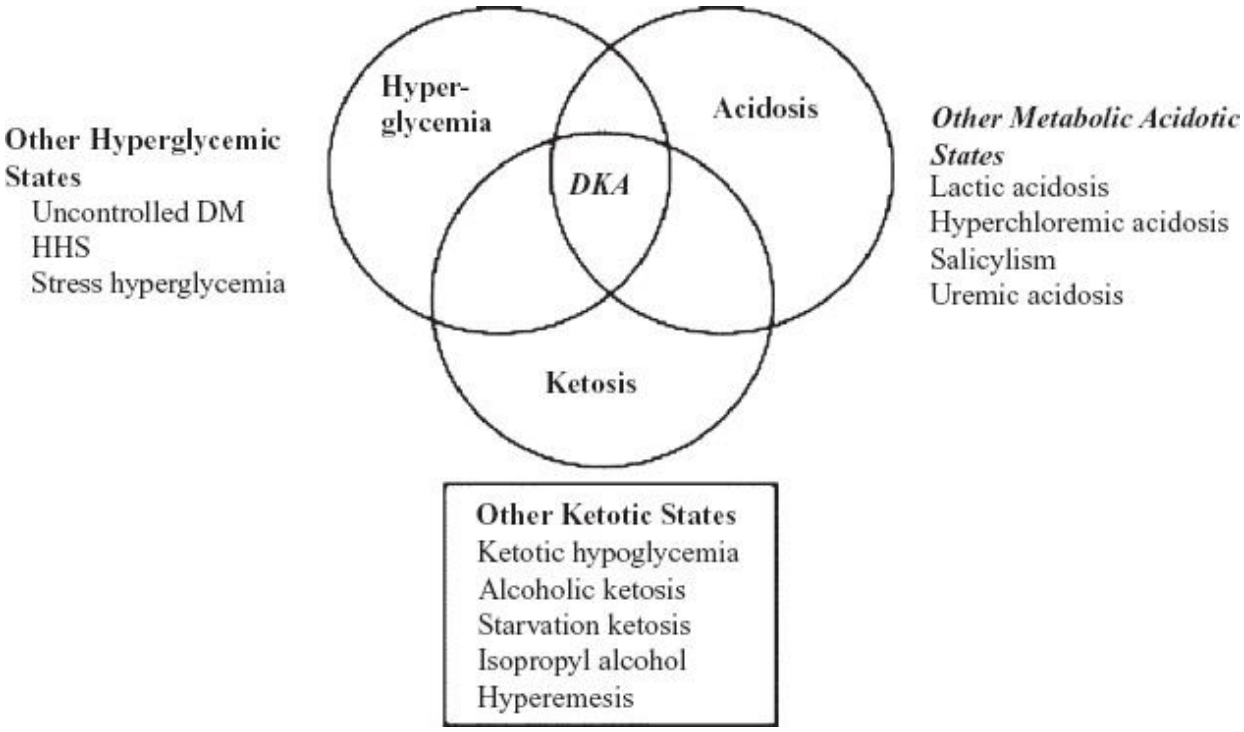

FIGURE 205.2 Differential diagnosis of diabetic ketoacidosis. (Adapted from Kitabchi AE, Fisher JN. Diabetes mellitus. In: Glew RA, Peters SP, eds. *Clinical Studies in Medical Biochemistry*. New York, NY: Oxford University Press; 1987:105.)

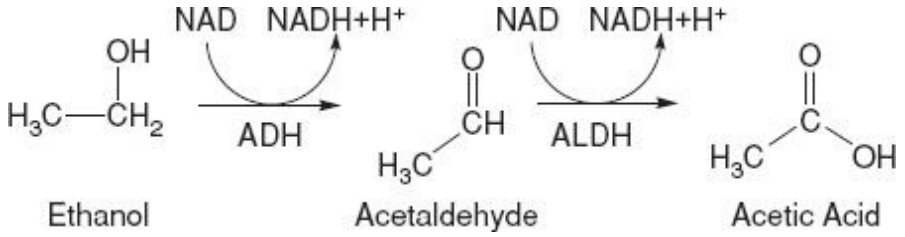

FIGURE 207.1 Alcohol is oxidized by alcohol dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH) to acetic acid, generating reduced NADH.

Alcoholic ketoacidosis (AKA) most closely resembles DKA but can usually be distinguished by history and the absence of the hyperglycemia typically present in DKA (see Chapter 207). Lactic acidosis arising from intra-abdominal pathology, and metabolic

acidosis resulting from toxic ingestions (salicylates, methanol, or ethylene glycol) are particularly important diagnoses to consider.

Because DKA and HHS are often precipitated by illnesses that result in high levels of stress hormones, an important consideration is whether a hyperglycemic crisis accounts for the entirety of the patient's condition or whether a concurrent acute condition is present. The coexistence of infection should be considered in essentially all patients in DKA and HHS; myocardial infarction should be considered in adults, and intra-abdominal pathology should be considered in all patients for whom abdominal complaints are prominent.

The differential diagnosis of the AMS that is typical of HHS, but may also occur with DKA, falls within the much broader differential diagnosis of AMS and decreased level of consciousness (see Chapter 11). The prompt measurement of a bedside glucose is appropriate for essentially all patients with AMS.

ED EVALUATION

Initial evaluation and management should begin simultaneously. If the patient appears critically ill, the ABCs (airway, breathing, and circulation) must be assessed and stabilized as electrocardiogram (ECG) and pulse-oximetry monitoring is begun. Oxygen administration can be guided by the physical assessment and pulse oximetry. Blood pressure should be measured, intravenous (IV) access should be established, and blood should be drawn for analysis. IV normal saline can be started if indicated by blood pressure, heart rate, and the brief physical assessment, if it is not contraindicated by a history of severe kidney disease or heart failure. A bedside blood glucose should be measured on any patient with AMS or in whom either hyper- or hypoglycemia is suspected. Only after these actions are rapidly initiated, which are appropriate for any seriously ill patient, should diagnosis-specific evaluation and treatment begin.

In many cases, a tentative diagnosis of a hyperglycemic crisis can be made within minutes of the patient's arrival. A history of diabetes, a bedside glucose >250 mg/dL, or both generally initiates the diagnostic investigation. Any patient with a history of diabetes

should be promptly questioned regarding medications, current adherence to the regimen, results of recent home glucose and urine-ketone monitoring, prior episodes of DKA or HHS, symptoms of DKA or HHS, self-treatment with oral fluids or additional insulin, and an estimate of oral fluid intake and urine output. In the setting of AMS, a baseline mental status and level of function should be determined. Eliciting a history of kidney or heart disease is also important to subsequent fluid management.

Because approximately 10% to 20% of cases of DKA and 30% to 40% of cases of HHS occur in patients without a history of diabetes, symptoms of a hyperglycemic crisis should be elicited from all patients whose presentation suggests the diagnosis. It is particularly important to try to identify the underlying precipitant, so that it can be addressed specifically, whether it is an infection, a myocardial infarction, a financial problem, a behavioral issue, or the failure of the caregiver to provide sufficient fluids to an immobile patient dependent on others for care. If the patient is unable to give the necessary history, other available sources, including family, caregivers, and paramedics, should be questioned.

A bedside glucose >250 mg/dL is highly sensitive but poorly specific for DKA. "Euglycemic DKA" has been described, but a presenting glucose was <180 mg/dL in only 1% of cases in a series of 722 consecutive episodes (17). A bedside glucose >500 mg/dL, particularly in the context of a history of diabetes, AMS, or both generally suggests HHS. On the other hand, most patients with an elevated glucose have uncontrolled diabetes and not a hyperglycemic crisis so additional evidence is necessary.

Hyperpnea in the presence of clear lungs and normal oxygen saturation support the diagnosis of DKA. The presence of level 3 to 4+ ketonuria on urinalysis greatly improves the specificity of the diagnosis (18), so urinalysis should be performed early in the assessment. In most cases, the history, physical examination, bedside glucose, and urine ketones are sufficient to guide therapy until lab results provide further confirmation. Newer alternative diagnostic strategies include use of venous blood gas electrolytes (19) and bedside measurement of capillary blood ketones using a ketone

meter (20). Both have acceptable sensitivity and specificity for initial screening, and available resources may dictate which modality is preferable at a given institution.

For many years, an ABG has been used to quickly establish the presence of acidosis. In DKA, the pH on a VBG and an ABG correspond closely, so a VBG may be substituted (21). An ABG is preferable only if there is concern for other conditions, such as ventilatory failure or salicylate intoxication, in which an arterial partial pressure of carbon dioxide (pCO_2) is useful. In less severely ill patients, the presence of the expected anion-gap metabolic acidosis of DKA can be determined using the serum bicarbonate and the calculated anion gap [$Na^+ - (Cl^- + HCO_3^-)$], and a blood gas is unnecessary.

Although a tentative diagnosis of HHS can often be inferred at the bedside, the diagnosis can be confirmed only on the basis of the biochemical data. In addition to hyperglycemia >600 mg/dL, the definition of HHS requires an *effective* serum osmolality >320 mOsm/kg (see Table 205.1). Osmolarity in mOsm/L is often calculated using the following formula: 2[Na (mEq/L)] + [glucose (mg/dL)]/18 + [BUN (mg/dL)]/2.8, with a normal value of 290 ± 5. This calculation includes urea, which diffuses freely across cell membranes and, therefore, does not create an osmotic gradient between the intracellular and extracellular spaces nor contribute to the pathogenesis of HHS (16). The calculated *effective* osmolarity excludes urea from the calculation: effective osmolarity (mOsm/L) = 2[Na (mEq/L)] + [glucose (mg/dL)]/18, with normal being 285 ± 5. With normal renal function, the contribution of the blood urea nitrogen (BUN) to osmolarity is small, and the difference between osmolarity and effective osmolarity is insignificant.

The initial laboratory evaluation should include STAT measurement of electrolytes, urea nitrogen, creatinine, glucose, serum osmolarity, serum ketones, and a urinalysis. The mean serum glucose of patients with HHS has been reported to be 930 mg/dL, which is much greater than the maximum measurable by a bedside glucose meter (~600 mg/dL), so the value must be confirmed by laboratory measurement (6). The anion gap should be calculated:

anion gap = [Na^+ − (Cl^- + HCO_3^-)]. The normal is 7 to 9 mEq/L. Serum magnesium, calcium, and phosphate are often measured but are less immediately essential.

Because of the simultaneous loss of water and electrolytes, admission laboratory data (Table 205.4) may not fully reflect the deficits. The osmotic diuresis and dehydration of DKA and particularly HHS may cause hypernatremia, but this may not be apparent from the measured serum sodium concentration. Hyperglycemia causes water to move from the intracellular into the extracellular space, thereby reducing the measured sodium concentration by dilution. This effect resolves as the hyperglycemia is corrected. It is common practice to "correct" for this dilutional effect by adding a factor of 1.6 to 2.4 mEq to the reported sodium concentration for every 100 mg of glucose >100 mg/dL. The corrected serum sodium is commonly used to guide fluid therapy. Dehydration also results in poor renal perfusion, which is reflected in an elevated BUN and creatinine. Also, underlying chronic renal insufficiency is common in HHS patients and older adult DKA patients.

TABLE 205.4
Typical Admission Biochemical Data in Patients Who Have Hyperglycemic Hyperosmolar Syndrome and Diabetic Ketoacidosis

Laboratory Test	HHS	DKA
Glucose (mg/dL)	930 ± 83	616 ± 36
Na^+ (mEq/L)	149 ± 3.2	134 ± 1.0
K^+ (mEq/L)	3.9 ± 0.2	4.5 ± 0.13
BUN (mg/dL)	61 ± 11	32 ± 3
Creatinine (mg/dL)	1.4 ± 0.1	1.1 ± 0.1
pH	7.3 ± 0.03	7.12 ± 0.04
Bicarbonate (mEq/L)	18 ± 1.1	9.4 ± 1.4
BOHB (mmol/L)	1.0 ± 0.2	9.1 ± 0.85
Total osmolality (mOsm/kg)	380 ± 5.7	323 ± 2.5
Anion gap	11	17

Data are presented as mean ± SEM.
HHS, hyperglycemic hyperosmolar syndrome, DKA, diabetic ketoacidosis.
Adapted from Kitabchi AE, Umpierrez GE, Murphy MB, et al. Management of hyperglycemic crises in patients with diabetes. *Diabetes Care*. 2001;24:131–153.

Urine and serum ketones aid in distinguishing HHS from DKA. The direct measurement of the serum β-hydroxybutyrate, the predominant ketone in DKA, is preferred over the older nitroprusside test. The nitroprusside test provides a semiquantitative estimate of acetoacetate and acetone but does not measure β-hydroxybutyrate, resulting in an underestimation of the severity of ketoacidosis.

A complete blood count (CBC) is routinely ordered, often with the intent of using the white blood cell count (WBC) to determine if infection is present. Unfortunately, an elevated WBC is typical in hyperglycemic crises. In DKA, only a WBC $>25{,}000$ or an elevated band neutrophil count has been shown to support a diagnosis of infection (22). A chest radiograph, urinalysis, blood and urine cultures, and sometimes a lumbar puncture are appropriate to evaluate for infection in HHS and in cases of DKA where infection is suspected as a precipitant or a comorbidity. Hemoconcentration can be expected to elevate the hemoglobin and hematocrit.

Additional laboratory testing should be individualized:

- An ECG is indicated if hyper- or hypokalemia, a dysrhythmia, or an acute coronary syndrome is suspected. A serum troponin is appropriate for select patients.
- The ordering of urine and blood cultures should be based on a reasonable suspicion of infection in cases of DKA, but is routine

when evaluating the typically elderly patient presenting in HHS.
- Chest radiography is only indicated if pulmonary or cardiac disease is suspected in DKA, but is almost uniformly indicated in HHS.
- The serum amylase and lipase are frequently elevated in DKA, even in the absence of clinical pancreatitis. Abdominal computed tomography (CT) findings correlate much better with clinical outcomes, making CT the test of choice for patients with severe or persistent abdominal pain. Intravenous contrast should generally be avoided.
- CT scan of the brain is indicated if there is AMS or focal neurologic abnormalities.
- A liver profile and toxicologic studies are sometimes useful.

KEY TESTING

- Bedside glucose (Accucheck)
- Urinalysis
- VBG or ABG
- Basic metabolic profile including electrolytes, BUN, creatinine, glucose
- CBC
- Serum ketones
- Serum osmolarity

ED MANAGEMENT

The management of hyperglycemic crises is directed at correction of the metabolic derangements and treatment of comorbidities (Fig. 205.3). Although the specifics of the individual patient's presentation should guide fluid, electrolyte, and insulin therapy, adherence to written protocols decreases variability of care and improves patient outcomes. Published protocols for the management of hyperglycemic crises are broadly available and have been adopted by many hospitals and health care organizations.

DIABETIC KETOACIDOSIS

Although the components of therapy remain the same across the spectrum of DKA, the aggressiveness of treatment depends on the severity. Patients in severe DKA typically require rapid infusion of large volumes of fluids and IV insulin. At the other end of the spectrum, patients with mild DKA may do well with only oral rehydration and subcutaneous (SC) insulin.

Fluid deficits average 6 L in DKA, making rehydration an essential first step. A liter of normal saline (0.9% NaCl) should be infused in 30 to 60 minutes. For most patients, the first liter should be followed by an additional 1 to 2 L of normal saline (0.9% NaCl) during the next 2 to 4 hours, with the infusion rate dictated by the patient's homodynamic stability and response to therapy, as reflected by the vital signs and urine output (1). This fluid restores circulating volume and tissue perfusion, which decreases circulating counterregulatory catecholamines and begins to reduce serum glucose and osmolality by restoring an osmotic diuresis. Water deficits are typically greater than the corresponding sodium and chloride deficits, so it is appropriate to change to 0.45% NaCl at 250 mL/hr after the initial 2 to 3 L saline infusion as blood pressure, pulse, and signs of tissue perfusion normalize. Patients found to have hypernatremia should be changed to 0.45% NaCl when the serum sodium results are obtained. This usually occurs after the first liter of normal saline has already infused. When the glucose has decreased to $<$250 mg/dL, IV fluids should be changed to dextrose 5% in 0.45 NaCl (D_5 0.45 NaCl) to prevent hypoglycemia. The infusion rate can be further reduced once the patient begins to drink, provided there is a brisk urine output and the metabolic derangements are resolving. The remaining fluid deficits are corrected in 1 to 2 days.

All patients should be reassessed frequently during treatment. The need for adequate fluid replacement must be balanced against the risk of volume overload, and particular caution is warranted in the elderly and patients with cardiac or renal compromise. Fluid management in pediatric DKA is controversial and is typically less aggressive than in adults (see Chapter 274). This caution is caused by concerns about clinically significant cerebral edema, which occurs in

approximately 0.7% to 1% of pediatric DKA episodes, but is rare in adults.

Insulin inhibits ketogenesis independent of its effects on glucose production and utilization and is essential for the correction of ketoacidosis and hyperglycemia. Treatment goals are the inhibition of ketone production and correction of hyperglycemia at a rate of 50 to 75 mg/hr. Although there are recent reports of the successful use of SC rapid-acting insulin (23) and intramuscular insulin was used in the past, IV insulin is preferred for the treatment of moderate to severe DKA. IV insulin provides predictable and titratable insulin levels. SC insulin, which is adequate for mild DKA, may be poorly absorbed in the setting of severe dehydration and hypotension. Patients using an insulin pump should remove the device when being treated with IV insulin.

Once hydration has begun, physiologic doses of insulin (regular insulin at 1 to 5 U/hr IV) are generally all that is required. Higher doses of 10 to 15 U/hr or more may be necessary in the setting of infection or other states in which there are high levels of counterregulatory hormones. Because of this variability, the recommended initial insulin-infusion rate is 0.1 U/kg/hr. If the decline in serum glucose is <50 mg/dL/hr, the insulin-infusion rate may be doubled.

Guidelines for the care of adult patients with DKA recommend an initial bolus of regular insulin 0.1 U/kg IV (1). On the other hand, pediatric guidelines no longer recommend an initial bolus, citing concern about excessively rapid correction of serum glucose (>100 mg/dL/hr) and osmolarity (>3 mOsm/kg/hr), and a potential increased risk of cerebral edema. If no insulin bolus is to be given to an adult patient, data suggest that a slightly higher insulin infusion rate of 0.14 U/kg/hr may reduce the number of patients who require supplemental insulin to achieve the target rate of decrease in glucose levels (24). Whether this is sufficient ground to justify either an initial bolus or a higher infusion rate is controversial. Insulin should be withheld until hypokalemia ($K^+ <3.3$ mEq/L) has been excluded. If hypokalemia is noted, an insulin bolus should be not be given and

the insulin infusion should be delayed until correction of the serum potassium is under way.

Ketonemia typically takes longer to resolve than hyperglycemia. To correct ketosis and avoid hypoglycemia, it is typically necessary to simultaneously infuse insulin and glucose. Protocols vary in the specifics of how this should be done, but it is common to change the IV fluids to dextrose 5% in 0.45 NaCl (D_5 0.45 NaCl) at 150 to 200 mL/hr when the blood glucose decreases to <250 mg/dL, and continue the insulin infusion at the same or a reduced rate of 0.5 U/kg/hr. It may be necessary to temporarily suspend insulin infusion to avoid impending or actual hypoglycemia, but prolonged withdrawal of insulin should be avoided since it almost invariably results in relapse of DKA.

Standard criteria for the resolution of DKA are a glucose <200 mg/dL, and two of the following: a serum bicarbonate ≤ 15 mEq/L, a venous pH >7.3, or an anion gap <12 mEq/L (1). Once DKA has resolved and the patient is able to eat, SC insulin is started. Patients should receive both long-acting (basal) insulin and rapid- or short-acting insulin given before meals or restarted on their insulin pump. The prior insulin dose, if known, provides a basis for restarting SC insulin, with the dose, time of administration, and caloric intake matching the patient's usual pattern. If the prior dose is unknown or if the patient was not previously on insulin, consultation with the physician who will be providing ongoing care is indicated.

A multiple daily-insulin regimen, using a basal/bolus approach of rapid-acting premeal insulin (aspart [NovoLog], lispro [Humalog], or glulisine [Apidra]) plus a basal insulin (glargine [Lantus] or detemir [Levemir]), or use of continuous SC insulin infusion (CSII or insulin pump therapy) with rapid-acting insulin is now common. Regular insulin plus neutral protamine Hagedorn (NPH) insulin, which is less expensive but may cause more hypoglycemia, is an alternative. To ensure adequate insulin levels and avoid relapse, SC insulin should be administered before stopping IV insulin. A delay of 30 to 60 minutes is recommended when using aspart or lispro insulin and 1 to 2 hours when administering regular insulin.

Most, but not all, patients with DKA are potassium-depleted, and deficits of 2 to 5 mEq/kg are common. The initial serum potassium is usually elevated, caused by acidosis and insufficient insulin effect, both of which result in intra- to extracellular potassium shift. Administration of IV fluids and insulin cause a decline in the serum potassium, caused by dilution, diuresis, and cellular uptake. To avoid serious symptomatic hypokalemia with dysrhythmias and respiratory-muscle weakness, insulin should not be administered until the potassium is known to be >3.5 mEq/L. IV potassium replacement is indicated for all DKA patients whose potassium is <5.3 mEq/L and who are urinating >50 mL/hr. A replacement rate of 10 mEq/hr is often sufficient to maintain a serum potassium of 4 to 5 mEq/L, but higher rates are indicated for a potassium level <3.5 mEq/L or when treating symptomatic hypokalemia. Patients who have consumed large amounts of potassium or who are in renal failure may not be potassium-depleted and may present with severe hyperkalemia. For this reason, potassium should generally not be administered until the serum potassium is known and the patient is urinating.

Three mechanisms contribute to the resolution of acidosis in DKA: (a) the suppression of the ketogenesis by insulin, (b) the diuresis of ketoacids via hydration, and (c) the oxidation of ketoacids by skeletal muscle, brain, and kidneys. Additionally, hyperventilation-induced respiratory alkalosis is an important compensatory mechanism. There is no clear evidence that the administration of sodium bicarbonate improves outcome even in severe DKA in adults or children. Bicarbonate corrects the arterial acidosis but not the intracellular or central-nervous-system acidosis. Bicarbonate also decreases tissue oxygen uptake, exacerbates hypokalemia, and is an osmolar load, thereby potentially contributing to the development of cerebral edema. It is broadly agreed that bicarbonate has no role in the management of mild to moderate DKA, and its use in severe DKA is controversial (1,25). If, despite these concerns, bicarbonate is administered, it should be diluted and administered as an infusion, not given in bolus injections.

Like potassium, phosphate is lost with the osmotic diuresis, so that patients in DKA have a phosphate deficit despite normal or increased initial serum levels. The deficit only becomes apparent if the phosphate is rechecked during the course of therapy. Eating replenishes phosphate, and randomized trials of IV phosphate replacement have not demonstrated benefit (1). Rapid administration of phosphate can cause hypocalcemia. Nonetheless, phosphate replacement is widely recommended in severe (1 mg/dL) or symptomatic hypophosphatemia. If it is to be given, potassium phosphate 20 to 30 mEq should be administered slowly in a dilute solution.

Infections, principally pneumonia, urinary tract infections, and sepsis, complicate approximately 35% of episodes of DKA. Other serious acute medical illnesses, including myocardial infarction and stroke, complicate an additional 15% of episodes. Comorbidities may precipitate DKA or be a consequence of its metabolic derangements. In either case, these conditions increase morbidity and mortality in DKA, and their effective management is essential.

The management of DKA in patients with renal failure is particularly difficult. Hyperglycemia and ketoacidosis may be severe even though fluid and electrolyte deficits are minimal or absent. Hemodialysis is often the only effective way to correct these abnormalities. The nephrology service should be consulted and arrangements should be made for hemodialysis in an ICU setting as soon the patient is recognized to have simultaneous renal failure and DKA.

Monitoring is an important component of the management of DKA, and is facilitated by using standardized protocols and flow sheets. Vital signs, fluid balance (IV fluid administration and urine output), insulin and other therapeutic interventions, and serial laboratory studies should be recorded. Glucose and potassium should be measured every 1 to 2 hours, and sodium and bicarbonate should be measured every 2 to 4 hours. There is generally no need to repeat serum ketones or blood gases after the initial assessment, if the patient is improving. Magnesium and phosphate should be assessed 4

to 8 hours after initiating therapy. If phosphate is given, calcium should be rechecked after treatment.

Most of the complications of the treatment of DKA are predictable and largely preventable. Hyperchloremic metabolic acidosis is frequently noted during treatment, but is generally clinically insignificant. Hyperchloremic metabolic acidosis can be minimized by switching the IV fluids to 0.45 NaCl after replenishing the intravascular space with normal saline. Hypokalemia can be minimized by replacing potassium aggressively, omitting an insulin bolus if the potassium is low, and avoiding bicarbonate. Hypoglycemia can be avoided by changing to D_5 0.45 NaCl when the glucose declines to <250 mg/dL. Fluid overload can be prevented by monitoring fluid balance and frequently reassessing the patient.

Neurologic deterioration during treatment of DKA, particularly in children, should prompt consideration of cerebral edema. Diminishing the risk of DKA-associated cerebral edema is problematic because the mechanism is complex and prevention strategies have not been prospectively validated. Nonetheless, the incidence of cerebral edema can probably be reduced and outcomes can be improved when it occurs by correcting hyperosmolarity slowly, monitoring mental status, and treating aggressively when cerebral edema is recognized. A confirmatory brain CT should not delay therapy.

HYPEROSMOLAR HYPERGLYCEMIC STATE

The management of HHS is directed at the replacement of fluids and electrolytes, the correction of hyperglycemia at a rate of 50 to 75 mg/hr, correction of hyperosmolarity at a rate not to exceed 3 mOsm/kg/hr, and the treatment of comorbidities. As noted previously, the ABCs should be assessed and stabilized as monitoring is initiated, vital signs measured, intravenous access established, and blood drawn for laboratory studies including bedside measurement of the blood glucose.

Fluid deficits average 9 L in HHS, making rehydration an essential first step. A liter of normal saline (0.9% NaCl) should be infused over an hour unless known congestive heart failure or severe renal

insufficiency dictate more cautious administration. Expansion of the intravascular volume with normal saline diminishes the serum glucose and osmolarity by dilution and reinitiates the osmotic diuresis curtailed by severe dehydration and poor renal perfusion. Patients who remain hypotensive after the first liter of fluid should continue to receive normal saline (0.9% NaCl), with the infusion rate dictated by the patient's response to therapy, as reflected by the vital signs and urine output. Fluid administration after the stabilizing resuscitation should be guided by the corrected serum sodium. Intravenous fluids should be changed to 0.45% NaCl for patients whose corrected serum sodium is normal or elevated. Patients who are hyponatremic should continue to receive 0.9% NaCl. When the glucose decreases to <300 mg/dL, intravenous fluids should be changed to D_5 0.45 NaCl to prevent hypoglycemia and a too-rapid decline of osmolarity.

The goal of fluid therapy is to replace half of the fluid deficit over 12 to 24 hours and the remainder over the next 24 hours. Even after an initial infusion of 1 to 2 L, subsequent infusion rates of 250 to 500 mL/hr are necessary to achieve this goal. The infusion rate can be reduced once the patient begins to drink if there is brisk urine output and the metabolic derangements are resolving. As with DKA, fluid management in pediatric HHS is less aggressive than in adults. This is due to concerns about clinically significant cerebral edema, which has been described as a complication of HHS in children.

Patients with HHS are typically significantly potassium depleted, with deficits commonly in the range of 4 to 6 mEq/kg. The initial serum potassium level, however, is usually normal or elevated. This is due to the relative insulin deficiency and mild metabolic acidosis that are often present in HHS, both of which result in intra- to extracellular potassium shift.

Administration of intravenous fluids and insulin cause a decline in the serum potassium and phosphate owing to dilution, diuresis, and cellular uptake. The ADA recommends managing potassium and phosphate in HHS according to the same guidelines used for DKA.

Insulin therapy should not be initiated until fluid resuscitation is well under way and the serum potassium is known. In HHS,

hyperglycemia and hyperosmolarity result in the net movement of water into the extracellular space, maintaining intravascular volume despite severe dehydration. Insulin administration results in the intracellular shift of both glucose and, with the resulting decline in extracellular osmolarity, water. Fluid therapy alone will result in decline of glucose averaging 25 to 50 mg/dL/hr and up to 200 mg/dL/hr, often achieving the target goals for the resolution of hyperglycemia and hyperosmolarity. The optimal insulin regimen in HHS has not been definitively determined. In the absence of definitive data, the ADA recommends the same insulin regimen for HHS as DKA.

Infections, principally pneumonia, urinary tract infections, and sepsis, complicate approximately half of HHS episodes, and it is appropriate to have a low threshold for initiating broad-spectrum antibiotics in the emergency department. Other serious acute comorbidities to consider include myocardial infarction and stroke.

Monitoring is also an important component of the management of HHS. Standardized protocols and flow sheets improve outcomes in DKA, and similar benefit is likely with HHS.

As with DKA, the complications of the treatment of HHS are predictable and largely preventable. Fluid overload is a potential complication of fluid replacement, particularly in patients with pre-existing heart failure or renal insufficiency. Patients should be reassessed frequently, and the need for adequate fluid replacement must be balanced against the risk of fluid overload. Particular caution is warranted in the elderly and patients with cardiac or renal compromise. Careful monitoring of fluids infused, urine output, vital signs, and laboratory parameters is essential. Hypokalemia can be minimized by replacing potassium aggressively and electing not to give an insulin bolus if the potassium is low. Hypoglycemia can be avoided by changing to D_5 0.45 NaCl when the glucose declines to $<$250 to 300 mg/dL. HHS-associated cerebral edema is managed in the same manner as DKA-associated cerebral edema.

CRITICAL INTERVENTIONS

- Assess and stabilize ABCs.

- Check a bedside glucose on all patients with AMS.
- Promptly begin aggressive fluid replacement, typically 2 L in the first 4 hours for DKA; fluid replacement can be more moderate in HHS, particularly in the presence heart failure or moderate to severe kidney disease.
- Provide sufficient potassium replacement, beginning when the patient is making urine and the serum potassium is ≤ 5.3 mEq/L for DKA.
- Avoid hypoglycemia and an excessive decline in osmolarity by changing IV fluids to D_5 0.45 NaCl when the serum glucose declines to 250 mg/dL.
- Maintain continuous insulin infusion until the anion gap is normal for DKA patients.
- Identify and treat comorbidities and precipitants.
- Monitor frequently until hyperglycemic crisis resolves and the patient resumes routine medications and is eating and drinking normally.

DISPOSITION

Patients with severe DKA, as indicated by pH <7.1, hypotension, anuria, coma, or need for intubation, should be admitted to an intensive care unit (ICU). Serious comorbidities and age >65 years increase mortality and should lower the threshold for ICU admission.

Location in the hospital for a patient with DKA often depends on where an insulin drip can be given and whether or not frequent monitoring of blood glucose levels is possible outside of an ICU setting. A monitored bed is appropriate for patients with moderate DKA and patients whose DKA was initially severe but has improved with ED therapy. A floor bed is appropriate only for patients whose episode is minor or has almost fully resolved. Patients whose DKA was initially only mild or moderate and was resolved in the ED may be considered for discharge home, if there are no important comorbidities. Safe discharge depends not only on the resolution of the metabolic derangements and the absence of ongoing precipitants

but also on the patient's level of competence for self-care, the available social support, and the availability of close follow-up.

Patients with severe HHS, as indicated by a decreased level of consciousness, seizures, hypotension, or hypothermia, should also be admitted to an ICU. A monitored bed setting is appropriate for awake patients with moderate HHS and for those in whom HHS has substantially improved with ED therapy. A floor bed is appropriate only for patients whose episode has almost fully resolved. Comorbidities should be considered when selecting a level of care. Patients with serious infections, cardiac or renal disease generally require an ICU admission.

Because of the need for immediate and closely monitored treatment for at least 24 hours, it is usually preferable to avoid transfer of hyperglycemic crises patients to another facility until after the metabolic derangements have been substantially corrected and any serious underlying illness has been fully stabilized.

Common Pitfalls

- Failure to check a bedside glucose on all patients with AMS.
- Failure to give adequate volumes of appropriate fluids, starting with 1 L of normal saline in the first hour for adult patients.
- Failure to give adequate IV insulin in severe DKA (0.1 to 0.14 U/kg/hr).
- Failure to manage potassium appropriately, either by administering insulin in the setting of hypokalemia, failing to adequately replace potassium as hypokalemia develops, or administering excessive potassium to patients who are anuric.
- Failure to monitor the blood glucose frequently and to switch to glucose-containing IV fluids when the blood glucose level declines to <250 mg/dL.
- Reliance on sodium bicarbonate to correct the acidosis of DKA.
- Failure to search for and treat precipitating causes and other comorbidities.

CHAPTER 206 Hypoglycemia

Scott R. Votey and Anne L. Peters

The *clinical syndrome* of hypoglycemia is defined as a low plasma glucose value (usually <55 mg/dL) accompanied by signs and symptoms of adrenergic excess (sweating, nervousness, tachycardia, shakiness) or alterations in mental status (or both) that are relieved by the administration of carbohydrate. The more recent realization that asymptomatic plasma glucose levels of 65 to 70 mg/dL impair defenses against subsequent more severe hypoglycemia in patients with diabetes mellitus has resulted in the broadening of the definition of hypoglycemia to a glucose level of <70 mg/dL (1). This definition, which includes both symptomatic and asymptomatic patients, is intended to include everyone for whom there is potential harm from the low glucose level. The glucose concentration at which *clinical* hypoglycemia occurs varies. Completely healthy women may have glucose levels <45 mg/dL during a fast without symptoms of hypoglycemia. Conversely, adrenergic symptoms of "hypoglycemia" may occur in patients without low blood glucose levels. Therefore, though the diagnosis of the clinical syndrome of hypoglycemia must be based on the presence of both biochemical hypoglycemia and concomitant hypoglycemic symptoms, physicians should be aware that glucose values of 55 to 70 mg/dL have important implications for patients with diabetes.

A balance between glucose utilization and production maintains normal blood glucose levels. In healthy individuals, preprandial blood glucose levels are usually 70 to 100 mg/dL, with a small postprandial rise peaking 1 hour after eating and returning to baseline within 4 hours. The major glucose-requiring tissues are the

brain and red blood cells. Muscle, fat, and a variety of other tissues take up glucose but are also capable of utilizing other fuels. The brain, with its absolute requirement for glucose, is what drives the need to maintain adequate blood levels of glucose. During fasting, glucose production occurs through hepatic glycogenolysis (breakdown of glycogen) and gluconeogenesis (biosynthesis of glucose from nonglucose substrates). Insulin levels are high in the postprandial period and fall with fasting.

Glucoreceptors in the hypothalamus sense low blood glucose levels and cause the secretion of counterregulatory hormones. Glucagon is the primary counterregulatory hormone in nondiabetic patients. Patients with established type 1 diabetes (T1DM) or advanced type 2 diabetes (T2DM) lose their glucagon response to hypoglycemia (2).

The onset of action of glucagon is rapid, and it acts by enhancing glycogenolysis and gluconeogenesis. If glucagon is not present, epinephrine serves as the major counterregulatory hormone. Epinephrine also has a rapid onset of action and acts by inhibiting glucose utilization by muscle, increasing gluconeogenesis, and inciting carbohydrate ingestion (2). Cortisol and growth hormone are secreted as part of normal hypoglycemic counterregulation, but their release is delayed, and they do not contribute to the acute recovery from hypoglycemia.

Although there are many causes of hypoglycemia, the vast majority of episodes encountered in the emergency department (ED) occur as complications of the treatment of diabetes with insulin, sulfonylureas, or meglitinides. Hypoglycemia is an important and growing concern for the approximately 26 million individuals with diabetes in the United States. The Diabetes Treatment and Control Trial (3) in 1993 and the United Kingdom Prospective Diabetes Study (4) in 1998 found that tight control of blood glucose delays the development and progression of microvascular complications in patients with both type 1 and type 2 diabetes, and 7- to 10-year follow-up from these studies has shown a reduction in cardiovascular events as well. From these and subsequent studies came a greater emphasis on maintaining tight glycemic control.

Unfortunately, tight glycemic control also increases the frequency of hypoglycemia, especially in patients treated with insulin (5,6). More recent data suggest that hypoglycemia increases the risk of cardiovascular death, potentially negating the benefits of tight control. The Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial published in 2008 demonstrated an increased risk of death from any cause and cardiovascular events in the intensively treated patients (7). The higher rate of death in the tight control group was possibly due to the increased use of insulin, very low HbA1c target (<6.0%), and higher rates of hypoglycemia. On the basis of these data and subsequent trials, it is reasonable to conclude that patients at highest risk for cardiovascular death (e.g., older, longer duration of diabetes, existing cardiovascular disease [CVD], or high risk for CVD) may not benefit from intensive therapy, and treatment should be individualized (8).

Goals for emergency physicians in the diagnosis and management of hypoglycemia are:

1. Recognition of each episode of hypoglycemia
2. Prompt and adequate treatment
3. Identification of the cause of the episode
4. Identification of the need for hospital admission to prevent recurrent episodes
5. Establishment of a plan to prevent future episodes for patients being discharged from the ED

CLINICAL PRESENTATION

The signs and symptoms of hypoglycemia fall into two categories: Adrenergic (those caused by increased activity of the sympathetic autonomic nervous system) and neuroglycopenic (those caused by depressed activity of the central nervous system [CNS]; Table 206.1). Although there is much individual variation, the adrenergic symptoms of hypoglycemia typically start as the blood glucose falls below 70 mg/dL, and evidence of neuroglycopenia occurs as the blood glucose falls below 55 mg/dL. Symptoms vary from person to person but, within an individual, remain fairly constant from episode to episode.

TABLE 206.1
Signs and Symptoms of Hypoglycemia

Adrenergic	Neuroglycopenia
Weakness	Headache
Tremor	Mental dullness
Sweating and warmth	Confusion
Tachycardia and palpitations	Amnesia
Nervousness	Incoordination
Irritability	Visual disturbances
Tingling of face and fingers	Seizures
Hunger	Coma
Nausea	Focal neurologic deficits

Patients may not experience the adrenergic symptoms of hypoglycemia (2). Patients who are recurrently hypoglycemic, particularly patients with tightly controlled T1DM or advanced T2DM, may not have symptoms until the blood glucose is <50 mg/dL and neuroglycopenic symptoms develop. This phenomenon, termed *hypoglycemia-associated autonomic failure* (HAAF), is the combined result of a downregulation of the adrenomedullary and sympathetic neural responses to hypoglycemia, owing to intensive insulin therapy or recent hypoglycemia (2,9). HAAF can develop in patients without symptomatic hypoglycemia as a result of glucose levels of 55 to 70 mg/dL. Patients who lack adrenergic symptoms often fail to recognize impending hypoglycemia and are at increased risk for severe neuroglycopenia. In many patients with HAAF, the epinephrine response to hypoglycemia can be restored by the careful avoidance of hypoglycemia for as little as 2 to 3 weeks (9). Because the CNS is almost entirely glucose-dependent for function, hypoglycemia manifests neurologically within minutes. Measurable cognitive deficits commonly begin at blood glucose levels <55 mg/dL, but some patients remain awake and alert at much lower levels (10). Patients may fail to perceive their cognitive dysfunction and deny having any CNS symptoms. The blood glucose at which seizures occur varies, but a seizure at a glucose of >40 mg/dL should prompt investigation for an alternative cause. Focal

neurologic deficits, including hemiparesis, are the presenting symptoms in a small percentage of patients (11).

Mild episodes of hypoglycemia (defined as episodes recognized and treated by the patient) consisting only of adrenergic symptoms should not dissuade patients from adequately treating their diabetes. On the other hand, recurrent severe episodes (involving altered mentation and requiring assistance to treat), particularly those resulting in loss of consciousness or seizures, may be associated with cumulative cognitive impairment in children (12) and adults (13).

Time to recovery and completeness of recovery depend on the severity and duration of hypoglycemia. Young children, the elderly, and patients with a history of prior brain injury, such as a stroke, appear to be at higher risk for a prolonged or incomplete recovery. Although not every episode of severe hypoglycemia will result in measurable cognitive decline, the potential for permanent injury mandates prompt diagnosis and treatment.

DIFFERENTIAL DIAGNOSIS

Although chronic treatment of diabetes with insulin, a sulfonylurea agent, or both is the root cause of the vast majority of hypoglycemic episodes encountered in the ED, there is invariably an acute precipitant perturbing the patient's usual glucose homeostasis. The key to preventing future hypoglycemic episodes is the identification of the precipitant of the current episode. A good history is the principal tool in achieving this goal and will identify the precipitant in approximately 50% of cases. Common precipitants can be grouped according to their physiologic mechanisms (Table 206.2). Inadequate glucose availability is the most commonly identified cause of hypoglycemia, followed by increased caloric utilization, medication error, and diminished excretion of a glucose lowering medication. Recurrent asymptomatic or minimally symptomatic hypoglycemia and the resultant HAAF are important risk factors for severe hypoglycemia (1,2,9).

TABLE 206.2
Precipitants of Hypoglycemia in Patients with Diabetes

Inadequate Glucose Availability

Decreased caloric consumption: Missed or delayed meal, fasting

Decreased hepatic gluconeogenesis: Suppression by alcohol, hepatic failure

Insufficient counterregulatory hormones: Glucagon, epinephrine, cortisol

Increased Caloric Utilization

Exercise

Illness and injury

Medications—Increased Insulin Effect

Accidental overdose: Poor vision, misunderstanding, change in syringe size, change in insulin concentration, pharmacy error

Intentional overdose

Diminished Excretion or Metabolism

Renal insufficiency: Insulin and sulfonylurea agents undergo renal excretion

Hepatic failure: Sulfonylurea agents undergo hepatic metabolism

Patients who take oral sulfonylurea agents can have prolonged periods of hypoglycemia (sometimes lasting up to a week) because of the long elimination half-life of many of these agents; this phenomenon occurs particularly in elderly patients and those with kidney disease or heart failure (14). The possibility of declining renal function should be assessed in any patient who develops recurrent or unexplained episodes of hypoglycemia while taking these agents. These individuals often require admission to the hospital. In addition, ingestions of even small doses of sulfonylurea agents may produce severe hypoglycemia in young nondiabetic children, and any sulfonylurea ingestion in these patients should be taken seriously (15).

The remaining antidiabetic agents vary in their propensity to cause hypoglycemia. The meglitinides repaglinide and nateglinide are short-acting insulin secretagogues that increase insulin secretion and may cause hypoglycemia. The hypoglycemia associated with these agents is of shorter duration than the hypoglycemia associated with the sulfonylurea agents; nevertheless, repaglinide and nateglinide can cause severe symptoms (e.g., seizure) if given after, instead of before, a meal (16).

Pramlintide, a synthetic analog of the human hormone amylin, suppresses postprandial glucagon secretion, slows gastric emptying,

and promotes satiety. Used in combination with insulin in type 1 and type 2 diabetes, it increases the risk of severe hypoglycemia if the premeal insulin dose is not appropriately reduced. Therefore, in all patients starting pramlintide, the instructions in the packet insert should be followed and premeal insulin doses reduced by 50%.

Conversely, metformin; the α-glucosidase inhibitors (acarbose and miglitol), the thiazolidinediones (rosiglitazone and pioglitazone); and the dipeptidyl peptidase IV (DPP-4) inhibitors (sitagliptin, saxagliptin, linagliptin, and alogliptin) rarely cause hypoglycemia when used alone. In combination with insulin or a sulfonylurea, however, these drugs may exacerbate an episode of hypoglycemia. Glucagon-like peptide (GLP-1) receptor agonists (short- and long-acting exenatide and liraglutide) are used solely as an adjunct to other antidiabetic medications. GLP-1 receptor agonists increase the risk of hypoglycemia when used with a sulfonylurea agent or insulin, but only rarely in conjunction with metformin.

Owing to frequent miscommunication among patients, pharmacists, and medical care providers about the currently available types of insulin, it is necessary to be familiar with these products (Table 206.3). Patients often confuse the type of insulin with the brand name, referring to their insulin as "Humulin," for instance, when they mean the "Lilly brand of human Neural Protamine Hagedorn (NPH) insulin." If patients have their insulin vials with them, it helps to look at them. If not, and they cannot name the insulins they take, it is helpful to remember that all the rapid- and short-acting insulins are clear, as are insulin detemir (Levemir) and insulin glargine (Lantus). NPH insulin and mixtures that contain NPH insulin are cloudy.

TABLE 206.3
Time Course of Action of Insulins[a]

Type	Onset	Peak	Duration
Rapid-Acting			
• Aspart (NovoLog)	5–15 min	30–90 min	3–5 hrs
• Glulisine (Apidra)	5–15 min	30–90 min	4 hrs
• Lispro (Humalog)	5–15 min	30–90 min	4 hrs
Short-Acting			
• Regular (Humulin R, Novolin R)	30–60 min	2–4 hrs	4–6 hrs
Intermediate-Acting			
• NPH (Humulin N, Novolin N)	3–4 hrs	8–14 hrs	16–24 hrs
Long-Acting			
• Detemir (Levemir)	2–4 hrs	None	6 (low dose)–24 (high dose) h
• Glargine (Lantus)	4–6 hrs	No discernible peak effect, but an increased effect may occur at 10–20 hrs	24–28 hrs
Mixtures			
• 70/30 (Two mixtures are marketed: 70% NPH + 30% regular, and 70% NPH + 30% Aspart)	Actions based on components of the mixture		
• 75/25 (75% NPH + 25% Lispro)			
• 50/50 Varies (50% X and 50% Y)			

[a]Times are approximate, as insulins may act differently in different individuals.

Some patients, particularly the elderly, are not aware that they are being treated for diabetes. Therefore, it is helpful to review all medications the patient is currently taking when investigating the cause of an unexplained episode of hypoglycemia. Surreptitious use of medication is a consideration in healthy-appearing patients with unexplained hypoglycemia, especially if it is severe or recurrent.

Aside from insulin and sulfonylurea agents, a number of other drugs can precipitate hypoglycemia, either at therapeutic doses or in overdose (Table 206.4). Patients taking β-blockers are at increased risk for severe hypoglycemia owing both to a blunted counterregulatory response and to diminished adrenergic symptoms when hypoglycemia does develop. Salicylate overdoses occasionally precipitate hypoglycemia, particularly in children.

TABLE 206.4
Selected Causes of Hypoglycemia

Fasting
Healthy-Appearing individuals
Drugs
Exogenous insulin
Oral hypoglycemic agents: Sulfonylurea agents, meglitinide agents
β-adrenergic blocking agents
Salicylates
Disopyramide
Quinine
Pentamidine
Others
Ethanol and other alcohols
Insulinomas and non–β-cell tumors
Inherited disorders of metabolism
Ill-Appearing individuals
Liver failure: Depleted glycogen stores and impaired gluconeogenesis
Chronic kidney disease
Adrenal insufficiency
Sepsis
Shock
Malnutrition, including anorexia nervosa
Congestive heart failure, especially severe right heart failure
Pregnancy
Fed (reactive)
Impaired glucose tolerance
Alimentary
Idiopathic reactive

Many serious illnesses may result in hypoglycemia in nondiabetic patients; the most common are sepsis, chronic kidney disease, liver failure, pneumonia, and congestive heart failure (16). Malnutrition, including anorexia nervosa and cancer-associated cachexia is another cause. The etiology is often multifactorial. Adrenal insufficiency itself rarely causes symptomatic hypoglycemia, but it may be a contributing factor during times of physiologic stress. Cortisol is

necessary for gluconeogenesis and, without it glucose levels (especially fasting levels) fall (see Chapter 209).

Ethanol ingestion can precipitate hypoglycemia in patients with or without diabetes by suppressing gluconeogenesis, usually in association with inadequate intake of food. This phenomenon occurs most commonly in children, malnourished chronic alcoholics, binge drinkers, and diabetics who neglect to eat adequately when consuming alcohol.

Insulinomas are a rare cause of hypoglycemia. Patients with these tumors have recurrent episodes of hypoglycemia, typically presenting with neuroglycopenic rather than adrenergic symptoms. Insulinomas often go undiagnosed for years. Weight gain from eating large amounts of food to self-treat the hypoglycemia is common. Non–β-cell tumors, including mesenchymal tumors, hepatocellular carcinomas, adrenal carcinomas, and others, can also produce hypoglycemia.

Newborns, especially premature infants, are at risk for hypoglycemia during times of physiologic stress owing to small glycogen stores and limited hepatic gluconeogenesis. In addition, several inborn errors of metabolism can cause hypoglycemia in children. These include glucose-6-phosphatase deficiency, galactosemia, hereditary fructose intolerance, and carnitine deficiency. Inborn errors of metabolism usually present in the first year of life. Infants experiencing unexplained hypoglycemia should be hospitalized and evaluated for these disorders.

Although hypoglycemia occurs most commonly in the fasting state, there are several causes of fed, or postprandial reactive hypoglycemia (18). Alimentary hypoglycemia occurs in patients who have undergone gastrointestinal surgery, most commonly gastrectomy and gastric bypass bariatric surgery (19). Patients have symptoms of hypoglycemia 30 to 120 minutes after eating. The hypoglycemia is thought to occur because of a more rapid emptying of food into the duodenum, leading to both an accelerated absorption of glucose and an exaggerated insulin response.

Some patients with “mild” diabetes, including patients treated with diet alone and those with risk factors for type 2 diabetes but

who have not yet been diagnosed as having diabetes, experience postprandial hypoglycemia. The insulin response to food is initially delayed; the enhanced insulin secretion that follows produces postprandial hypoglycemia.

Idiopathic reactive hypoglycemia is a rare disorder that is substantially over-diagnosed, particularly in young women. In general, patients with this diagnosis have adrenergic symptoms on fasting or postprandially but are rarely documented to have a glucose <50 mg/dL.

ED EVALUATION

In the ED, the biochemical diagnosis of hypoglycemia is usually made by using a bedside glucose meter. A blood glucose level should be checked immediately on any patient presenting with adrenergic or neuroglycopenic symptoms, including behavioral abnormalities, decreased level of consciousness, and acute focal deficits. An immediate check should be done on patients with syncope and trauma patients in whom hypoglycemia as a precipitant may be overlooked.

Most glucose meters are now calibrated to give results that are consistent with plasma glucose levels, but plasma glucose levels measured in the laboratory are still considered the most accurate determination of the blood glucose level, particularly in critical care settings (20). In addition, arterial blood has a glucose level 5% to 10% higher than that of venous blood. Test strips and meters are highly sensitive for the diagnosis of hypoglycemia but may give falsely *high* readings in the setting of severe anemia and hypotension.

A number of substances interfere with glucose measurement. The severity of interference varies with the specific meter (20,21). For example, in the setting of high levels of acetaminophen glucose measurements using meters which rely on the glucose oxidase method may be falsely low, whereas meters which utilize the glucose dehydrogenase method may be falsely elevated (20).

Test strip accuracy also deteriorates with prolonged storage, so strips should not be used beyond their printed expiration date.

Despite all of these potential confounders, meters are sufficiently accurate so that the laboratory confirmation of hypoglycemia diagnosed by bedside testing is usually not necessary, when the results are consistent with the clinical picture.

After the patient has recovered adequately, a focused history should be taken, investigating the cause of the episode, including the timing and doses of medications, food eaten, and activity. For diabetic patients, the history should include an assessment of diabetic control, whether home glucose monitoring is performed, usual values, and the frequency and severity of hypoglycemic episodes. The presence of comorbidities, including kidney disease, liver disease and heart failure, should be ascertained.

Additional laboratory testing, including measurements of the serum creatinine or hepatic transaminases, is necessary only if the history fails to reveal the cause of the episode and contributory comorbidities are suspected.

Hypoglycemia has been associated with silent and symptomatic myocardial ischemia and infarction in diabetic patients both with and without known coronary artery disease (22). The possibility that an episode of hypoglycemia has induced myocardial ischemia should be considered in all diabetic patients at risk for coronary artery disease.

Nondiabetic patients who are suspected of having hypoglycemia, but for whom the diagnosis was not established in the ED can be referred for an outpatient diagnostic workup.

KEY TESTING

- Bedside glucose

ED MANAGEMENT

Hypoglycemia should be considered in every patient with an altered sensorium or any acute neurologic deficit. Ideally, a fingerstick blood glucose level should be obtained to confirm the diagnosis before treatment with glucose is initiated, but glucose should be given empirically if the level cannot be obtained immediately. Although

animal studies and retrospective human studies have found a correlation between hyperglycemia and poor neurologic outcome among patients with stroke and severe brain injury, there is no evidence that the doses of glucose given to correct hypoglycemia are harmful. Only 20 g of carbohydrate is generally required to restore euglycemia, although, occasionally, more is required. Glucose can be administered orally or intravenously, depending on the patient's level of consciousness.

The initial treatment for a confused or comatose adult with hypoglycemia is a 50-mL bolus of 50% glucose intravenously. Less concentrated glucose solutions are recommended for children (25%) and neonates (10%) owing to concerns about hyperosmolality. The mean increase in the serum glucose level after this bolus is 150 mg/dL, but it varies greatly and is not predictable (23). The bolus should be followed by the continuous infusion of 5% or 10% glucose at a rate sufficient to keep the glucose level over 100 mg/dL until the patient is capable of eating. If there is any reason to suspect thiamine deficiency, thiamine 100 mg intravenously should be given concomitantly with glucose to avoid precipitating Wernicke–Korsakoff syndrome.

Patients who are alert enough to eat may be treated with glucose tablets or gel, orange juice, hard candy, or any form of concentrated sugar. If a patient is taking an α-glucosidase inhibitor (acarbose or miglitol), absorption of oral carbohydrate may be inhibited. These patients must be treated with dextrose (which is in glucose tablets) as opposed to sucrose (which is in table sugar). They can also be effectively treated with milk, because the drug does not inhibit lactase.

Adults with hypoglycemia who are unable to eat and in whom intravenous access cannot be secured can be given glucagon 1 mg intramuscularly. Children should receive 0.5 mg. Available data have shown glucagon to be safe and effective in restoring euglycemia (24), with neurologic recovery occurring generally within 10 minutes.

Adrenergic symptoms respond to glucose therapy within minutes. The time to recovery of neuroglycopenic symptoms is more variable, ranging from minutes to (in rare cases) days (10). A patient failing to

show clear signs of neurologic recovery within 10 minutes should have the glucose level rechecked to verify that euglycemia has been restored, because an additional bolus of glucose is occasionally needed. Alternative etiologies should be considered if there are no signs of neurologic recovery within 30 minutes.

To prevent recurrence, a meal or snack should be given after treatment. The simple carbohydrate given to raise the blood glucose level quickly does not produce a sustained elevation of blood glucose (50 mL of D50 and an 8-oz glass of orange juice contain only about 100 calories each), so a more complete meal, containing protein, fat, and complex carbohydrate, should be given to produce a more sustained rise in blood glucose levels. If hypoglycemia is due to administration of a long-acting insulin or a sulfonylurea agent, low glucose levels will typically last for an extended time. It is important to continue treatment and close observation to prevent relapse.

Octreotide, a synthetic peptide analog of somatostain, is a useful supplement to dextrose for the treatment of sulfonylurea-induced hypoglycemia in patients who are experiencing refractory or recurrent hypoglycemia despite routine management (25). Octreotide has no established role in the management of hypoglycemia caused by insulin overdose.

Long-term therapy depends on the cause of the hypoglycemia. If the hypoglycemia is secondary to a disorder such as hepatic failure or adrenal insufficiency, treatment of the underlying disorder is necessary to prevent recurrent hypoglycemia.

Dietary therapy is the treatment of choice for reactive and alimentary hypoglycemia. Patients should avoid sugars and eat frequent small snacks that contain a mixture of carbohydrate, fat, and protein. Restricting carbohydrate intake to 40% of total calories also may help.

In insulin-treated patients who become hypoglycemic, whether the usual insulin dose should be adjusted depends on the severity of the reaction. If the reaction is minor (easily detected and treated by the patient) and there is an explanation for the reaction (e.g., a missed meal or increased exercise), no insulin dose adjustment is indicated. However, if the reaction is more severe or is unexplained or if there

is a pattern of hypoglycemia occurring at the same time each day, the insulin dose should be decreased. Close monitoring of blood glucose levels is necessary to prevent hypoglycemia or hyperglycemia when the insulin dose has been changed.

Because recurrent hypoglycemia acutely downregulates the adrenergic response to additional episodes of hypoglycemia, a moderately severe episode of hypoglycemia will induce hypoglycemia unawareness on subsequent days, resulting in a more severe episode. Therefore, on the day after a moderate-to-severe hypoglycemic episode, the insulin dose should be reduced by 25%. Patients should be instructed to contact their primary care provider as soon as possible regarding subsequent insulin dosing.

CRITICAL INTERVENTIONS

- Administer glucose based on patients' symptoms rather than waiting for laboratory confirmation of hypoglycemia.
- Feed patients in the ED after a response to intravenous glucose.
- Administer glucagon to any hypoglycemic patient with neuroglycopenic symptoms who is unable to take oral glucose and in whom intravenous access has failed.
- Admit patients with hypoglycemia secondary to sulfonylurea agents or long-acting insulin preparations.

DISPOSITION

Most patients seen in the ED for hypoglycemia meet discharge criteria (Table 206.5). Hospital admission is indicated for patients failing to meet these criteria. Hypoglycemic patients with type 2 diabetes require hospitalization more frequently owing to the need for monitoring in patients with sulfonylurea-induced hypoglycemia, poor general condition, and a higher rate of concomitant disease requiring treatment (14).

TABLE 206.5
Discharge Criteria After a Symptomatic Hypoglycemic Episode

Brief episode
Full neurologic recovery
Able to eat
No major comorbidities that require hospital admission
Cause of the episode found and addressed
Treatment plan to prevent future episodes understood by the patient
Hypoglycemia accidental
Relapse unlikely—no long-acting insulin or oral agent nor prolonged excretion or metabolism
Ability to do home glucose monitoring[a]
Responsible person to be with the patient[a]
Follow-up arranged[a]

[a]Imperative for severe episodes requiring assistance for recovery.

Patients who are discharged should receive specific instructions on how best to avoid recurrent episodes (most commonly by increasing caloric intake or decreasing the insulin dose), should be instructed to perform self-monitoring of blood glucose, and should carry some form of oral glucose at all times. Family members of patients who have experienced a severe episode requiring assistance should be instructed in how to recognize and treat hypoglycemia, including use of a glucagon emergency kit. All patients with diabetes who take medications that predispose to hypoglycemia should be encouraged to wear a medical alert bracelet.

Common Pitfalls

- Failure to consider hypoglycemia in all patients with acute neurologic or psychiatric symptoms, including stroke-like symptoms, regardless of any history of diabetes.
- Failure to consider hypoglycemia in any physiologically stressed infant.
- Failure to follow a bolus of intravenous glucose with a continuous glucose infusion in patients who remain unable to eat.
- Prematurely discharging a patient whose episode of hypoglycemia is due to a long-acting insulin or a sulfonylurea agent.
- Failure to consider intentional overdose as the cause of hypoglycemia.

- Failure to consider that hypoglycemia may have induced clinically significant myocardial ischemia.
- Failure to reinforce the need for self-monitoring of blood glucose and, in particular, failure to discuss the need for monitoring blood glucose levels before driving.

CHAPTER 207 Alcoholic Ketoacidosis

Sage W. Wiener and Robert S. Hoffman

Americans consume 6.8 L of pure alcohol (ethanol) per capita each year, equivalent to more than 30 gallons of beer. A total of 15 to 20 million are problem drinkers, and alcohol is responsible for the death of 100,000 people each year in the United States (13). Alcohol dependency commonly results in malnutrition and toxicity to multiple organ systems. When alcohol-dependent patients become ill and are unable to tolerate oral intake, they are at greater risk than other patients because of their underlying diseases and the recent metabolism of alcohol. Alcoholic ketoacidosis (AKA) is a common result.

The chronic consumption of alcohol leads to substantial metabolic derangements. Unlike most drugs and toxins, alcohol is itself an energy source, and alcoholic patients may come to depend on this source for as much as half of their daily caloric intake (13). This leads to nutritional deficiencies, most notably of vitamin B_1 (thiamine) (3). Because the two-carbon molecule of alcohol cannot be utilized for anything other than energy production or fatty acid synthesis, these patients become glycogen-deficient.

AKA is a condition that results from these derangements, typically during a period of alcohol abstinence that immediately follows a drinking binge. As in diabetic ketoacidosis (DKA), the lack of glucose substrate leads to the production of the “ketone bodies” acetoacetate and β-hydroxybutyrate as alternate energy sources. Unlike in DKA, the underlying problem is not the absence of insulin preventing glucose utilization (although relative insulin deficiency

may play a role), but rather the absence of glucose substrate because of malnutrition and lack of glycogen. Alcohol metabolism shifts the redox state of the body toward a more reduced state by generating nicotinamide adenine dinucleotide (NADH) (Fig. 207.1). High concentrations of NADH cause the equilibrium between lactate and pyruvate to shift, favoring lactate (Fig. 207.2). Gluconeogenesis is inhibited in alcoholics, further limiting available glucose, because pyruvate is the initial substrate. Low glucose concentrations lead to low concentrations of insulin, so hormone-sensitive lipase is disinhibited. The result is lipolysis, releasing free fatty acids that are broken down to acyl-coenzyme A, subsequently forming ketone bodies (10,12,13).

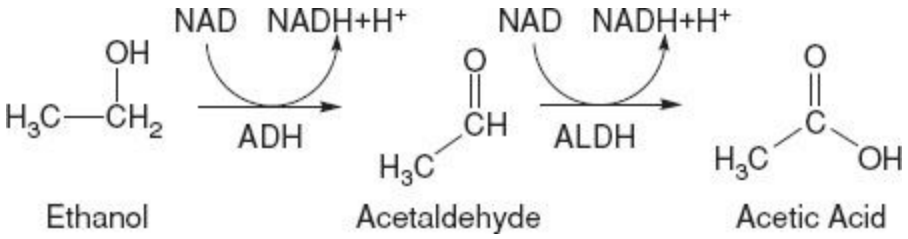

FIGURE 207.1 Alcohol is oxidized by alcohol dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH) to acetic acid, generating reduced NADH.

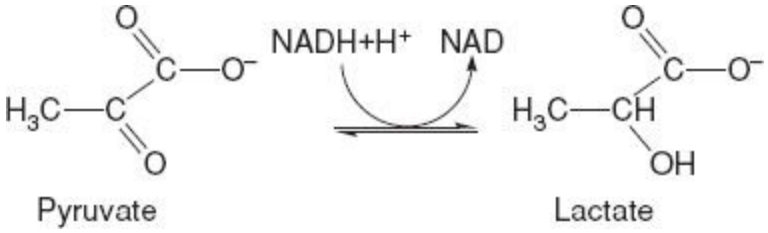

FIGURE 207.2 The relative concentrations of pyruvate and lactate are also governed by the redox state (the ratio of NAD to NADH). When the body is reduced (high levels of NADH), there is insufficient pyruvate for gluconeogenesis.

Although significant morbidity may result from coexisting medical disorders (6,7), once recognized, AKA generally responds well to therapy and has a low mortality rate in the hospital.

However, sudden cardiac arrest may occur even after initiation of medical care (23). A Danish prospective study of medicolegal autopsies in alcoholics found that 7% of deaths in their population could be attributed to AKA (18). This suggests that overall mortality from this disorder is higher than previously thought, possibly because many patients do not come to medical attention.

CLINICAL PRESENTATION

Patients generally present with nausea and vomiting and have abdominal pain suggestive of gastritis or pancreatitis. Vital signs are significant for tachypnea, tachycardia, and orthostatic hypotension. Patients tend to have significant volume depletion (several liters or more) caused by decreased oral intake, vomiting, osmotic diuresis from ketone bodies, and increased insensible losses from tachypnea, a compensatory response to metabolic acidosis (10). Their breath may have a characteristic fruity odor of ketosis. Although metabolic acidosis with an elevated anion gap (caused by the presence of unmeasured ketoacid anions) is always present, the serum pH may be normal or even elevated (22). This is because mixed acid–base disorders are common, including metabolic alkalosis from vomiting, contraction alkalosis from volume depletion, and compensatory respiratory alkalosis (10). Severe acidemia with a serum pH as low as 6.7 has been reported in fatal cases (6). Serum or urine ketones are typically only weakly positive, even in severe AKA (6). This is because the nitroprusside reaction used to measure ketones can only detect the functional ketone group of acetone or acetoacetate. Although often called a “ketone body” because it is in equilibrium with acetoacetate, β-hydroxybutyrate is not a true ketone and is missed by this test (Fig. 207.3). As in the case of the lactate–pyruvate ratio, the reduced redox state of the alcoholic patient causes the equilibrium to favor β-hydroxybutyrate. As patients improve with treatment, the NADH/NAD^+ ratio shifts to favor the production of acetoacetate, and ketones may actually appear to rise (4).

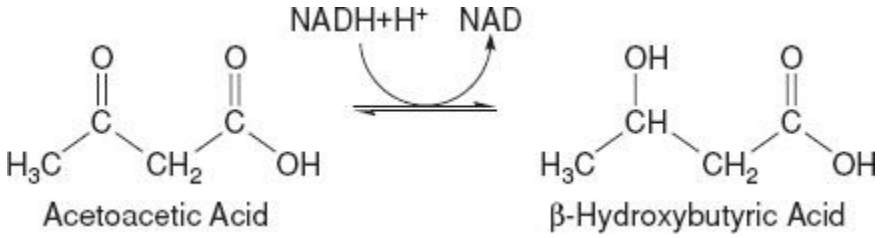

FIGURE 207.3 The relative concentrations of the "ketone bodies" acetoacetate and β-hydroxybutyrate depend on the redox state (the ratio of NAD^+ to NADH) of the body. Note that β-hydroxybutyrate is not a true ketone.

Electrolyte abnormalities are also common, particularly hypomagnesemia, hypophosphatemia, hypocalcemia, and hypokalemia (10,15,22). Hypoglycemia may be profound. If hypoglycemia is unrecognized, it may lead to substantial morbidity (11). Other abnormalities on laboratory evaluation (e.g., liver enzymes, pancreatic lipase and amylase), although common, are typically a result of associated illness, rather than being primary manifestations of AKA.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of anion-gap metabolic acidosis in the alcoholic patient is extensive. The familiar, although incomplete, MUDPILES mnemonic for causes of anion-gap acidosis includes methanol, metformin, uremia, DKA and other ketoacidoses, such as starvation ketosis and AKA, paraldehyde, phenformin, iron, isoniazid, ibuprofen, lactate, ethylene glycol, and salicylates. Common causes of acidosis in the alcohol-dependent population include elevated lactate from seizures or sepsis, AKA, and (much less frequently) toxic alcohols such as methanol and ethylene glycol.

Metabolic acidosis with an elevated lactate concentration, a marker of anaerobic metabolism, may be produced by many disorders including infections, ischemia, or hypoxia, which can lead to decreased oral intake and precipitate AKA. Illnesses such as pancreatitis, pneumonia, sepsis, Wernicke encephalopathy, and hepatic dysfunction are associated with an elevated lactate

concentration, and are therefore commonly seen in the alcoholic, as in other patients (8).

The distinction between alcoholic and other ketoacidoses is primarily based on history. A history of diabetes mellitus in the setting of ketoacidosis suggests DKA. Serum glucose elevation also suggests DKA, although hyperglycemia sometimes occurs in AKA, and DKA may rarely present with euglycemia (9). Significant acidosis caused by starvation is uncommon in the developed world and is usually a result of hyperemesis gravidarum, hunger strikes, or other similar causes of prolonged decrease in oral intake. A history of alcohol dependence should immediately suggest a diagnosis of AKA in the ketotic patient. Rubbing alcohol (isopropanol) ingestion also causes ketosis because it is metabolized to acetone. Because acetone does not undergo further metabolism to an organic acid, isopropanol ingestion does not cause a metabolic acidosis (see Chapter 283).

Methanol and ethylene glycol (see Chapters 299 and 300) are metabolized to the carboxylic acids formate, glycolate, and oxalate and may cause an anion-gap metabolic acidosis in the alcohol-dependent patient. Late findings in methanol poisoning include visual changes ranging from blurred vision to total blindness. In ethylene-glycol poisoning, acute kidney injury is the feared late complication. Unless the patient presents late enough to have end-organ toxicity, or there is a known history of ingestion of these substances, this diagnosis is difficult to establish, because timely concentrations are not available in most hospitals.

The serum alcohol concentration provides important information but is frequently misinterpreted. Most importantly, an undetectable alcohol concentration does not exclude a diagnosis of AKA; rather, it supports the diagnosis. Patients generally do not develop AKA until oral intake ceases. In contrast, the presence of any significant alcohol concentration (~100 mg/dL or more) almost excludes toxic alcohols as a source of metabolic acidosis because alcohol blocks alcohol dehydrogenase and prevents the metabolism of toxic alcohols to their carboxylic acid metabolites. Except in the rarely reported event of a patient drinking a toxic alcohol, waiting several

hours, and drinking alcohol before presenting, patients with significant alcohol concentration should not be able to generate a metabolic acidosis.

A further source of confusion is the osmol gap, a screening test for toxic alcohols. The serum osmolality can be significantly elevated in AKA, and an elevated osmol gap does not necessarily indicate the presence of a toxic alcohol (1,17). Toxic alcohol poisoning should be considered if there is a known history of ingestion, if there are signs of end-organ toxicity with acidosis (although temporary blindness has also been reported in association with AKA), or if other causes of an increased anion gap have been excluded.

Rapid improvement following intravenous fluids and dextrose is typical of AKA, and the anion gap generally returns to baseline after several hours (7,10,22). Such a response does not occur in toxic alcohol poisoning and most other conditions causing anion-gap acidosis (except reversible elevations of lactate concentration that might occur with a seizure or transient hypoperfusion). Without specific therapy, the anion gap would be expected to rise after toxic alcohol ingestion.

ED EVALUATION

The history should include the time, amount, duration, and pattern of prior alcohol consumption; circumstances that prevented continued consumption; the time of onset, nature, and severity of symptoms; prehospital treatment; and past medical history. The physical examination should focus on the vital signs, cardiopulmonary and neurologic status, assessment of the abdomen, and hydration status. If the patient's mental status is abnormal, as occurs in 15% of AKA patients (10), the bedside rapid reagent glucose should be checked early, because alcohol inhibits gluconeogenesis and is frequently associated with hypoglycemia (11,14). The patient should also be assessed for clinical signs of Wernicke's encephalopathy. Electrolytes, including calcium, magnesium, and phosphate, and an alcohol concentration should be sent, and a urinalysis should be performed.

AKA is usually first considered once the electrolytes reveal an elevated anion gap (4,16,21). The next step is to send a blood gas with lactate, because causes of an elevated lactate concentration occur commonly with metabolic acidosis. The blood gas is often performed on arterial samples, although a venous sample is probably adequate (2). If the lactate concentration does not account for the anion-gap elevation, urine or serum ketones should be checked. Once the diagnosis of AKA is established, it is important to look for any precipitating factors that led to the patient's condition. Further evaluation (see Key Testing) should be guided by the patient's signs and symptoms.

KEY TESTING

- Serum chemistry (electrolytes, BUN, creatinine, glucose)
- Serum calcium and magnesium (if not included in chemistry panel)
- Liver enzymes
- Serum lipase
- Serum ketones
- Complete blood count (CBC)
- Blood gas (venous or arterial)
- Serum or blood lactate
- Blood cultures
- Urinalysis
- Urine culture
- Stool guaiac
- Chest radiography
- Consider lumbar puncture (if suggested by the patient's signs and symptoms)
- Consider computerized tomography of the abdomen (if suggested by the patient's signs and symptoms)

ED MANAGEMENT

Advanced life support measures should be instituted as needed. Airway and breathing difficulties are rarely caused by AKA,

although associated alcohol withdrawal or severe respiratory infections may warrant endotracheal intubation. Specific therapy includes fluids, glucose, and thiamine administration. Intravenous crystalloids should be given to restore intravascular volume and to promote the renal clearance of ketones from the blood. In severely ill patients, a central venous catheter or ultrasound may be helpful in assessing volume status and response to treatment, particularly in those patients with underlying cardiac, hepatic, or renal disease.

Glucose is given to correct the underlying cause of AKA, which is primarily the lack of glucose and glycogen stores and relative insulin deficiency. Glucose provides energy substrate and stimulates insulin release from the pancreatic β-islet cells (6,7,10,12). Insulin, once released, inactivates hormone-sensitive lipase. This process leads to decreased release of free fatty acids, the substrates for ketogenesis. Thus, glucose is able to stop ketone formation. In the rare cases of AKA with significant hyperglycemia, dextrose may be withheld, but is necessary with euglycemia to invoke a brisk insulin response. The rapid reagent glucose should be followed closely, and insulin should be considered (9). Glucose should initially be given intravenously as 5% dextrose, unless the patient is significantly hypoglycemic, in which case a 50% dextrose bolus is indicated. Food should be given as soon as tolerated.

Thiamine is required for the utilization of glucose in the Krebs cycle, and the chronic administration of dextrose without thiamine has been reported to precipitate or worsen acute Wernicke encephalopathy (20). A dose of 100 to 200 mg should be administered intravenously (3) because alcohol-dependent patients do not absorb oral thiamine well (19).

Associated problems may require additional therapy. Abnormal electrolytes (potassium, phosphate, and magnesium) should be corrected. Although patients may have significant acidosis, sodium bicarbonate is unnecessary and should be avoided. The acidosis typically resolves rapidly once fluids and glucose are repleted (6,7,15,22). Insulin is an unnecessary intervention, unless the patient has a known history of diabetes mellitus or persistent hyperglycemia (which would suggest relative insulin deficiency and

impaired clearance of ketones) (6,7,10,22). Treatment of underlying or intercurrent medical problems should be instituted.

CRITICAL INTERVENTIONS

- Administer intravenous crystalloids to correct salt and water depletion.
- Administer intravenous dextrose to provide nutritional substrate and reverse ketosis unless the patient is severely hyperglycemic; feed patients who are able to eat.
- Administer parenteral thiamine (100 to 200 mg).
- Correct electrolyte abnormalities such as hypokalemia, hypomagnesemia, and hypophosphatemia.
- Avoid the use of sodium bicarbonate and insulin.
- Identify and treat associated precipitating medical illness (e.g., infections, pancreatitis, gastritis, alcoholic hepatitis).

DISPOSITION

In the hospital, AKA has low morbidity and mortality and responds well to treatment. The symptoms and metabolic derangements of mild AKA may often be corrected in a short time in the emergency department. Because of this prognosis, some authors have advised that most patients can be safely discharged with close follow-up. In one series, only 54% of patients with AKA were admitted (22). However, AKA occurs only in patients with a significant degree of alcohol dependence and nutritional deprivation. These patients are at high risk and cannot be relied upon to follow up appropriately. Coexisting medical illness is common. Rapid discharge from the emergency department without an evaluation for precipitating factors may be potentially dangerous. In the absence of severe electrolyte abnormalities, most patients with symptoms that do not resolve or whose precipitating event cannot be determined should be admitted to an observation or low-acuity bed.

Common Pitfalls

- Failure to appreciate that patients with AKA may have an undetectable serum alcohol concentration and trace or absent serum and urine ketones.
- Failure to identify and treat associated or precipitating medical illness (e.g., infection, pancreatitis, and hepatitis).
- Underestimating the degree of salt and water depletion.
- Failure to administer supplemental dextrose.
- Failure to recognize that the normal anion gap is diminished in hypoalbuminemia.
- Misdiagnosing AKA as DKA, usually because of incomplete history.
- Failure to administer thiamine or failure to appreciate that thiamine may not be absorbed by the oral route in patients with AKA.
- Inappropriately using insulin or sodium bicarbonate to treat AKA.

CHAPTER 208 Thyroid Emergencies

Adam G. Field

Recognizing thyroid disorders in the emergency department can be a diagnostic dilemma as the presentation can often be very subtle with vague symptoms such as depression, constipation, mild dyspnea, cough, weight gain or loss, anorexia, and palpitations. With more severe thyroid illness like thyroid storm, the diagnosis can also be elusive as the symptoms can often mimic other life-threatening diseases that present with clinical signs of a hyperadrenergic state including sympathomimetic toxidromes, sepsis, severe opiate or alcohol withdrawal. With severe hypothyroidism, the symptoms may mimic several medical conditions including hypothermia, septic shock, congestive heart failure, primary central nervous system (CNS) events, or a variety of other toxic metabolic syndromes. It is important not to have an anchoring bias to your first diagnosis, as life-threatening stressors such as infection, stroke, or myocardial infarction can either mimic or independently precipitate the onset of a thyroid emergency. A thorough review of the vital signs as well as a complete history and physical examination are imperative to identifying thyroid disease.

THYROID PHYSIOLOGY

Thyroid hormones regulate basal metabolic rate, protein synthesis, bone growth, and increase the body's sensitivity to catecholamines. The thyroid is made up of follicular cells that produce thyroid hormone and parafollicular cells that secrete calcitonin. Calcitonin and parathyroid hormone, which are made by chief cells in the

parathyroid gland, control plasma calcium and phosphate levels. Patients therefore, after thyroidectomy, often present to the emergency department with signs and symptoms of hypocalcemia.

There are two biologically active thyroid hormones: thyroxine (T_4) and triiodothyronine (T_3). T_4 and T_3 are both produced by the thyroid gland, but the majority of T_3 (approximately 60% to 80%) is produced by deiodination of the outer phenyl ring of T_4 in peripheral tissues. Several physiologic and pathologic stimuli influence thyroid hormone synthesis as well as conversion of T_4 to the more biologically active compound T_3. T_3 is three to four times more potent than T_4 and is therefore administered with more caution during severely decompensated hypothyroidism.

T_4 and T_3 are stored in the protein thyroglobulin and readily synthesized and released from the thyroid when needed. T_4 and T_3 that are bound in the serum to TBG (thyroxine-binding globulin) are referred to as total T_4 and T_3. Approximately 1% of T_4 and T_3 is free T_3 and free T_4 which are unbound thyroid hormones. Free T_3 and T_4 are the active hormones and subsequently these are the values that, in addition to TSH, are most often measured in the emergency department evaluations for thyroid dysfunction. TBG is affected by many factors including medications, disease states, and pregnancy. If one uses total T_3 and T_4 levels as a measure of thyroid function, this could lead to many false positives and negatives as these values are directly related to the amount of TBG available.

Sufficient iodine stores are necessary for the production of thyroid hormone. Iodine is transported into follicular cells which then oxidizes and binds to thyroglobulin. The iodinated thyroglobulin forms monoiodotyrosine and diiodotyrosine, which are then coupled to form T_3 and T_4. Iodine has several effects on thyroid function. Iodine deficiency and excess can cause hyper- or hypothyroidism. The effect of iodine depends on whether a patient is previously iodine-deficient, the etiology of thyroid dysfunction, and the rate and amount of iodine administered. As a clinician, one must be aware of potential sources of excess iodine so as not to precipitate

thyroid dysfunction in a patient with previously existing thyroid disease. Exogenous iodine may come in the form of amidarone, over-the-counter cold medications, or iodinated contrast material. The use of any of these products can decrease the effectiveness of nuclear thyroid imaging and therefore delay definitive diagnostic and treatment options (1,2). The use of iodinated contrast has also been shown to precipitate thyroid storm.

Thyroid hormone production is regulated by two mechanisms. The first mechanism is a feedback loop between the hypothalamic–pituitary axis and the thyroid gland. Thyroid stimulating hormone (TSH), which is secreted from the pituitary gland, increases production and secretion of T_4 and T_3 by the thyroid gland. Secretion of TSH from the pituitary is stimulated by thyrotropin-releasing hormone (TRH) from the hypothalamus. Extra thyroidal conversion of T_4 to T_3 is regulated by nutrition, other hormones, concomitant illness, and by the need for the body to increase its basal metabolic rate.

The hypothalamic–pituitary–thyroid access is considered a negative feedback loop as TSH and TRH levels decrease if more T_4 and T_3 is produced, and secreted, and increases with decreased levels of thyroid hormone. Hence, with primary hyperthyroidism, there is a high T_3 and/or T_4 with a low TSH, and with primary hypothyroidism, a low T_3 and T_4 with a high TSH. There are some exceptions with TSH levels when thyroid dysfunction is due to disease in the pituitary and the feedback loop is disrupted.

Thyroid function in the emergency department is assessed by measuring TSH and free T_4 (Table 208.1). Free T_3 measurement is only rarely indicated if there is a high clinical suspicion for thyrotoxicosis with normal free T_4 levels. This is referred to as T_3 thyrotoxicosis.

TABLE 208.1
Interpretation of Thyroid Function Tests

TSH	Free T_4	Disease State
Normal	Normal	None
Normal	Low	Euthyroid hypothyroxemia; severe nonthyroidal illness
Normal	High	Euthyroid hyperthyroxemia
Low	Normal	Subclinical hyperthyroidism; T_3 toxicosis (rare)
Low	Low	Central hypothyroidism; euthyroid sick syndrome
Low	High	Thyrotoxicosis
High	Normal	Subclinical hypothyroidism
High	Low	Primary hypothyroidism
High	High	TSH-mediated hyperthyroidism

Adapted from Supit EJ, Peiris AN. Interpretation of laboratory thyroid function tests for the primary care physician. *South Med J*. 2002;95(5):481–485.

HYPERTHYROIDISM

Hyperthyroidism is due to an increased production of thyroid hormone from the thyroid gland. Thyrotoxicosis refers to any state with increased circulating thyroid hormone whether it is from overproduction, excess release, or exogenous ingestion. The prevalence of hyperthyroidism in the United States is approximately 1% to 2%. The incidence of thyroid storm is about 1% to 2% of all patients with thyrotoxicosis. The incidence of hyperthyroidism is higher in areas with low iodine intake. In areas of high or normal iodine intake, the most common etiology is Graves disease, whereas in low iodine intake areas it is nodular goiter.

Graves disease is associated with increased circulating thyroid-stimulating antibodies which bind to thyroid receptors and increase the production of thyroid hormone. It is more common in females by a ratio of 10:1. It is often associated with several unique physical characteristics including Graves ophthalmopathy and dermopathy (see Clinical Presentation section). Graves disease is the most common thyroid illness associated with thyroid storm.

Toxic adenoma is a single thyroid nodule that excretes excess amounts of thyroid hormone, whereas multinodular goiter (TMNG) is associated with at least two or more thyroid nodules that produce excess thyroid hormone. Patients with a toxic adenoma as well as TMNG may present with thyrotoxicosis, subacute hyperthyroidism,

or euthyroid. TMNG is more common with advanced age and is the number one cause of hyperthyroidism in adults over 55 years of age. It can occur in younger patients but usually in areas where there is significant iodine deficiency. TMNG accounts for over 50% of cases of thyrotoxicosis in iodine-deficient areas (3). The symptoms are typically more gradual in onset than those of Graves disease. Like Graves disease however, it is more common in women than in men.

Thyroiditis is an inflammatory process that causes follicular disruption and release of thyroglobulin and stored thyroid hormone without de novo synthesis. Thyrotoxicosis is usually transient and is followed by hypothyroidism and then recovery. Hyperthyroidism does not usually persist since ongoing synthesis of thyroid hormones is inhibited due to TSH suppression. There are several etiologies of thyroiditis. Subacute thyroiditis and infectious thyroiditis are associated with acute illness with thyroid pain. Painless thyroiditis is associated with no pain as well as thyroid dysfunction and/or goiter (4).

Subacute thyroiditis is usually post viral and is thought to have an autoimmune basis. It often presents with hoarseness, dysphagia, and a painful goiter. As mentioned above, the hyperthyroidism is transient and usually progresses to a euthyroid and then hypothyroid phase. The hyperthyroid phase only lasts about 2 to 6 weeks. About 15% of patients remain hypothyroid, whereas others return to a euthyroid state if all of the thyroid gland has not been destroyed. This cycle typically takes about 6 to 12 months (4). It often follows an upper respiratory infection, tends to be seasonal, and has been associated with adenovirus, coxsackie, Epstein–Barr, and influenza viruses. It occurs more often in females and is more common in the 40- to 50-year age range. It is often associated with an elevated sedimentation rate and C-reactive protein (3).

Painless thyroiditis is associated with mild transient symptoms that typically resolve without treatment. It is due to lymphocytic infiltration of the thyroid gland and is usually associated with a painless goiter. There are several causes of painless thyroiditis including drug induced and Hashimoto thyrotoxicosis.

Hashimoto thyrotoxicosis is a form of painless thyroiditis. This disease process is typically associated with hypothyroidism (discussed below) but may have a transient hyperthyroid phase which is referred to as hashitoxicosis. In one study of patients with autoimmune thyroiditis, only 11% developed hashitoxicosis and the range of symptoms lasted from 31 to 168 days (3). A small percentage of these patients may develop hashitoxicosis encephalopathy, which is characterized by a subacute onset of confusion with altered level of consciousness, seizures, and myoclonus. This complication typically responds to corticosteroids and immunosuppressive therapy.

Thyroiditis can also be induced by medications, acute bacterial infections, iodine, radiation, trauma, as well as a postpartition state. Suppurative thyroiditis is a bacterial infection in the thyroid gland that can rarely be a life-threatening cause of thyroiditis. It can occur by direct inoculation through intravenous drug use, esophageal rupture, interventional procedures, and hematogenous spread. Patients that are predisposed include immunocompromised, elderly, and those with neck trauma, thyroid malignancy, and anatomic variants in the thyroid (3,4).

Common drugs that may precipitate thyroiditis include lithium, amiodarone, interferon-alpha, and interleukin-2 (Table 208.2). Iodine-induced thyroiditis can be in the form of amiodarone or radiographic contrast media. Radiation-induced thyroiditis occasionally occurs when a patient with Graves disease is being treated with radiation which can lead to destruction and inflammation of follicular cells. This may be associated with transient worsening of hyperthyroidism and a painful thyroid. Trauma-induced thyroiditis can occur after parathyroid surgery or direct blunt trauma to the neck. This usually presents as neck pain with transient hyperthyroidism. Other causes of thyrotoxicosis include exogenous ingestion, TSH pituitary secreting adenomas as well as primary and metastatic tumors within the thyroid that cause a destruction-induced thyrotoxicosis (2). A more extensive list of all the causes of thyrotoxicosis is listed in Table 208.3.

TABLE 208.2
Drugs Causing Alteration in Thyroid Function Testing

Decrease TSH Secretion

Glucocorticoids: inhibit TSH release

Dopamine: blocks TSH release

Octreotide: inhibits TSH release

Alter Thyroid Hormone Secretion

Decrease thyroid hormone secretion: iodide, amiodarone, lithium

Increase thyroid hormone secretion: iodide, amiodarone

Decrease T_4 Absorption

Cholesystramine, colestipol, sucralfate, ferrous sulfate, aluminum hydroxide, omeprazole

Alter T_4 and T_3 Transport in Serum

Increase serum TBG: estrogens, heroin, methadone, mitotane, fluorouracil

Decrease serum TBG: androgens, anabolic steroids

Displacement from protein-binding sites: furosemide, salicylates, heparin

Alter T_4 and T_3 Metabolism

Increase hepatic metabolism: phenobarbital and rifampin

Increase hepatic metabolism and displace from binding proteins: phenytoin and Carbamazepine

Cytokine Mediated

Interferon (5)

TABLE 208.3
Causes of Thyrotoxicosis

Graves disease
Toxic multinodular goiter
Toxic adenoma
Gestational hyperthyroidism
Chorionic gonadotropin induced
Physiologic hyperthyroidism of pregnancy
Trophoblastic tumors
Iodide-induced hyperthyroidism
Struma ovarii
Metastatic functioning thyroid carcinoma
TSH-secreting pituitary tumors
Thyroiditis
Lymphocytic thyroiditis (silent, painful, and postpartum)
Autoimmune: Hashimoto disease with Hashitoxicosis
Subacute thyroiditis (postviral, granulomatous, painful)
Drug-induced thyroiditis (amiodarone, lithium, interferon-α, interleukin-2)
Suppurative or infectious thyroiditis
Exogenous thyroid hormone
Thyrotoxicosis factitia (ingestion of natural products containing thyroid hormone)
Hamburger: thyrotoxicosis (related to using the neck of a cow to make hamburger patties)

Modified from Melmed S, Polonsky KS, Reed Larsen P, et al. Thyrotoxicosis. In: Mandel SJ, Larsen Reed P, Davies TF, eds. *Williams Textbook of Endocrinology*. 12th ed. Philadelphia, PA: Elsevier Saunders; 2011:362–402.

CLINICAL PRESENTATION

Thyrotoxicosis has a wide spectrum of presentations ranging from subclinical and apathetic hyperthyroidism to overt hyperthyroidism and thyroid storm. It affects most organ systems and is also associated with unique physical findings. The severity of concomitant stressors or precipitating infections may determine how dramatic the initial clinical signs and symptoms will be. The classic symptoms typically include tachycardia, weight loss, irritability, excessive sweating, anxiety, and heat intolerance. Please see Table 208.4 for a more complete list of clinical signs and symptoms.

TABLE 208.4
Signs and Symptoms of Thyrotoxicosis

General
- Excessive sweating
- Flushing
- Heat intolerance
- Weight loss
- Gynecomastia
- Irritability
- Dyspnea

Cardiovascular
- Palpitations
- Tachycardia
- Atrial fibrillation
- Systolic hypertension
- Congestive heart failure

Head/Neck
- Ophthalmopathy (Graves)
- Goiter

Gastrointestinal
- Abdominal pain
- Anorexia or increased appetite
- Diarrhea

Neurologic
- Nervousness
- Hyperreflexia
- Tremor

Muscular
- Muscle weakness
- Myalgias, myopathies
- Periodic paralysis (rare)

Dermatologic
- Hair loss
- Velvety skin
- Palmar erythema

These classic symptoms are often more obvious in younger than older patient populations. Older patients may present with vague or isolated symptoms making the diagnosis much more difficult (1). Beware in the elderly as up to 40% of this population with hyperthyroidism exhibit no tachycardia, defined as a heart rate over 100 (6).

Skin manifestations can include loosening of nails from the nail bed (Plummer nails), pruritis and hives (primarily with Graves), hyperpigmentation due to increased ACTH from accelerated cortisol metabolism, vitiligo, hair loss, and palmer erythema. Infiltrative dermopathy occurs in fewer than 5% of patients with Graves disease. These lesions cause hyperpigmented, nonpitting induration of the skin on the legs which are commonly over the pretibial area and dorsa of the feet (1).

Eye examination can demonstrate lid lag and stare. Lid lag is identified on physical examination if the sclera can be seen above

the iris when the patient looks down. Graves disease, which is the most common cause of hyperthyroidism is associated with unique eye findings referred to as Graves ophthalmopathy (Fig. 208.1). Autoantibodies target fibroblasts around the eye resulting in inflammation of the extraocular muscles and orbital fat. This causes proptosis and impairment of extra ocular motor function. Corneal ulcers and diplopia may result from this as well (1).

FIGURE 208.1 Patient with active thyroid-associated ophthalmopathy. Features exhibited include conjunctival hyperemia, periorbital edema, upper-lid retraction, and exophthalmos. (From Gold DH, Weingeist TA. *Color Atlas of the Eye in Systemic Disease*. Baltimore, MD: Lippincott Williams & Wilkins; 2001.)

Neck examination may demonstrate a thyroid goiter, which may be tender in patients with subacute thyroiditis. Massive thyroid enlargement may be found with Graves disease, toxic multinodular goiter, or painless thyroiditis. A small palpable nodule may also be seen with a thyroid adenoma. Associated symptoms with large goiters include dysphagia, mild dyspnea, or stridor.

Examination of the cardiopulmonary system can give several diagnostic clues. Respiratory rate and work of breathing is increased due to increased oxygen consumption and muscle fatigue. Hyperthyroidism can exacerbate underlying asthma. Cardiac and

peripheral vascular examination demonstrates a widened pulse pressure with systolic hypertension and signs of decreased peripheral vascular resistance.

Congestive heart failure can occur with severe hyperthyroidism or may be exacerbated in patients with pre-existing heart failure. Mitral valve prolapse occurs more frequently in patients with Graves and Hashimoto disease. With the use of bedside ultrasound in the emergency department, other findings such as increased left ventricular mass, mitral regurgitation, and signs of pulmonary hypertension may be appreciated (7). Pulmonary hypertension may be secondary to increased sympathetic tone, blood volume, and cardiac output, which can lead to pulmonary vasoconstriction and increased pulmonary arterial pressure (8).

The most common cardiac complications of thyrotoxicosis are atrial fibrillation and other atrial dysrhythmias, which can occur in 10% to 20% of patients with hyperthyroidism. The increased frequency of atrial fibrillation in elderly patients with thyrotoxicosis is thought to be due to the increasing incidence of cardiac disease independently in this age group. Atrial fibrillation can often be the only clinical sign in the elderly and is estimated to be present in up to 20% to 35% of older patients suffering from hyperthyroidism (9). Attempts to cardiovert atrial fibrillation should be deferred until the fourth month of maintaining a euthyroid state, because more than 56% of atrial fibrillation spontaneously reverts to sinus rhythm by this time. Medical or chemical cardioversion is usually successful in the remaining patients once a euthyroid state is obtained, except if there are other secondary causes as may be seen in the elderly (1,10).

Gastrointestinal manifestations include weight loss secondary to increased metabolism, abdominal pain, and vomiting. Occasionally, patients may gain weight with mild cases of hyperthyroidism because of increased appetite stimulation with a lesser degree of increased metabolic rate. Patients may develop symptoms of malabsorption as well as marked increased frequency of bowel movements. Liver function tests may be affected as well.

Many hematologic disorders may be associated with hyperthyroidism. Patients may exhibit a normocytic anemia. Graves disease may be associated with autoimmune hematologic disorders such as idiopathic thrombocytopenic purpura and pernicious anemia. A hypercoagulable state may develop from excess prothrombotic factors. Major thromboembolic complications such as pulmonary emboli are responsible for 18% of deaths caused by thyrotoxicosis (8).

Multiple electrolyte and laboratory abnormalities may exist as a result of the hypermetabolic state associated with thyrotoxicosis. Pre-existing diabetics may have increased difficulty with blood sugar control secondary to increased metabolic demands and associated biochemical changes. Increased lipolysis and ketogenesis can lead to lactic acidosis and ketoacidosis. Sodium, potassium, and chloride levels are not typically affected with hyperthyroidism but rarely hypokalemic periodic paralysis may be seen with thyrotoxicosis. Correction of the thyrotoxic state and hypokalemia will typically correct this process. Renal failure can rarely develop due to accelerated glomerular filtration rate which can lead to glomerulosclerosis and proteinuria. Renal insufficiency can also occur with severe thyrotoxicosis due to rhabdomyolysis or urinary retention from bladder dysfunction (8).

Calcium and phosphorous metabolism may also be affected by thyrotoxicosis. Increased osteoclast activity as well as increased excretion of calcium in the stool and urine can lead to accelerated osteoporosis and increased risk of fractures. Occasionally, hypercalcemia may be present with severe thyrotoxicosis as well.

Alteration in reproductive function as well as sexual maturation is also associated with thyrotoxicosis. Female patients may have altered cycles or amenorrhea. Increased rates of infertility as well as increased risk of miscarriage are associated with thyrotoxicosis. In males, increased conversion of testosterone to estradiol can result in clinical signs of decreased libido, erectile dysfunction, and decreased sperm production (1).

Neuromuscular and psychiatric abnormalities may be mistaken for other disease processes. Patients typically present with personality

changes, anxiety, emotional unstability, psychosis, and depression. These symptoms can sometimes mimic a patient with schizophrenia, manic depression, or attention-deficit disorder (1). Neurologic symptoms may include excessive body movements, hyperreflexia, proximal muscle weakness, and myopathy. Fine muscle tremors may be confused for new-onset Parkinson disease. Seizure activity is increased as well in this patient population (1).

The symptoms of hyperthyroidism may vary depending on the patient population. Two-third of older adults with hyperthyroidism present similarly to young patients with symptoms of sympathetic overactivity. One-third of elderly patients present with apathetic hyperthyroidism characterized by subtle symptoms such as lethargy, weight loss, and constipation. Shortness of breath, poor blood sugar control, leg edema, and heart failure may be the only diagnostic clue. Studies demonstrated a higher proportion of older adults reporting only one or two symptoms versus five or more in the younger patients. The lack of clinical signs of hyperthyroidism in older adults ($\leq$70 years) has been confirmed by several studies. Because of the vague symptoms, other diagnoses are often considered before entertaining the possibility of thyroid disease (9,11).

In pregnancy hyperthyroidism is associated with other pregnancy-specific clinical findings such as spontaneous abortion, premature labor, low birth weight, preeclampsia, and heart failure. Gestational thyrotoxicosis in early pregnancy can occur in 1% to 3% of cases and is associated with elevated HCG levels. It can present as hyperemesis gravidarum with symptoms of severe dehydration, weight loss, and ketonuria. Patients however should have other signs of thyrotoxicosis besides hyperemesis to warrant thyroid function testing (12). Hyperthyroidism can also present as a complication of pregnancy post partum. Postpartum thyroiditis (PPT) is an autoimmune, destructive inflammation of the thyroid gland that typically occurs within 1 year postpartum. The classic presentation of PPT starts with transient hyperthyroidism in the first 6 months postpartum, followed by transient hypothyroidism, then a return to the euthyroid state by 1 year postpartum (12).

One other factor to consider with regard to the pregnant patient with hyperthyroidism is the concomitant presentation of thyrotoxicosis in the neonate. It occurs more commonly in pregnancies complicated by Graves disease. Of the offspring born to women with Graves disease, 1% to 5% are affected with hyperthyroidism. High fetal heart rates, fetal goiter, poor growth, and craniosynostosis are some of the clinical features. With severe thyrotoxicosis in the neonate, high-output cardiac failure may develop (12).

Thyroid Storm

Thyroid storm is a life-threatening form of thyrotoxicosis associated with high temperatures of 104° to 106°F, severe tachycardia (>140), and CNS dysfunction with delirium, agitation, stupor, and coma. Other symptoms include severe dyspnea, abdominal pain, vomiting, and diarrhea. Additional clinical findings are the same as those described above (under Clinical Presentation of thyrotoxicosis) but may be more pronounced. Thyroid storm and severe thyrotoxicosis will be used interchangeably throughout the rest of this discussion.

Thyroid storm is often precipitated by surgery, trauma, infection, childbirth, or any other severe physiologic stressors. Thyroid surgery in patients with uncontrolled hyperthyroidism is used to be the most common precipitant of thyroid storm, but it now appears to be a severe infection (9). Thyroid storm has also been reported with discontinuation of antithyroid drugs, excessive ingestion or intravenous administration of iodine (e.g., radiocontrast dyes, amiodarone), radioiodine therapy (RAI), and even pseudoephedrine and salicylate use. Salicylates may increase free thyroid hormone levels and therefore should be avoided as a treatment option with thyroid storm (Table 208.5) (2).

TABLE 208.5
Precipitants of Thyroid Storm

Infection
Surgery/trauma
Vigorous palpation of the thyroid gland
Thyroid hormone ingestion
Cerebrovascular accident
Congestive heart failure
Pulmonary embolism
Diabetic ketoacidosis
Parturition
Toxemia of pregnancy
Emotional stress
Iodinated contrast dyes
Pseudoephedrine
Amiodarone

In addition to being a precipitant of overt hyperthyroidism, cardiac dysrhythmias, hypercoagulopathy, stroke, and pulmonary embolism may also be the end result of a thyroid storm.

It is important to have a high clinical suspicion for this disease process and to initiate early treatment. If thyroid storm is not recognized and treated on an emergent basis, hypotension and death can occur from cardiovascular collapse. Mortality rate is increased by 20% to 30% in this population. Table 208.6 shows a scoring system to help determine severity of presentation (2).

TABLE 208.6
Diagnostic Criteria for Thyroid Storm

Thermoregulatory Dysfunction	
Temperature (°F)	
99–99.9	5
100–100.9	10
101–101.9	15
102–102.9	20
103–103.9	25
≥104.0	30
Central Nervous System Effects	
Absent	0
Mild (agitation)	10
Moderate (delirium, psychosis, extreme lethargy)	20
Severe (seizure, coma)	30
Gastrointestinal–Hepatic Dysfunction	
Absent	0
Moderate (diarrhea, nausea/vomiting, abdominal pain)	10
Severe (unexplained jaundice)	20
Cardiovascular Dysfunction	
Tachycardia (beats per minute)	
99–109	5
110–119	10
120–129	15
130–139	20
≥140	25
Congestive heart failure	
Absent	0
Mild (pedal edema)	5
Moderate (bibasilar rales)	10
Severe (pulmonary edema)	15
Atrial fibrillation	
Absent	0
Present	10
Precipitant history	
Negative	0
Positive	10
TOTAL SCORE	
Scoring System	
>45: Highly suggestive of thyroid storm	
25–44: Suggestive of impending storm	
<25: Unlikely to represent thyroid storm	

In patients with severe thyrotoxicosis, points are assigned to the highest weighted description applicable in each category and scores totaled. When it is not possible to distinguish the effects of a concurrent illness from those of the severe thyrotoxicosis, points are awarded to favor the diagnosis of storm and empiric therapy.

With permission from Burch HB, Wartofsky L. Life-threatening thyrotoxicosis: Thyroid storm. *Endocrinol Metab Clin North Am* 1993;22:263–277.

DIFFERENTIAL DIAGNOSIS

As mentioned in the introduction, thyroid storm and severe thyrotoxicosis have similar presentations to many other life-threatening processes including the following: sympathomimetic (i.e., cocaine and methamphetamine) and anticholinergic toxidromes, malignant hyperthermia, salicylate overdose, alcohol, opiate and benzodiazepine withdrawal, multisystem trauma, sepsis, serotonin syndrome, exsanguination from ruptured viscous, pheochromocytoma, and psychotic break. Each of these clinical presentations has unique characteristics that may help differentiate them from a thyroid storm. For example, thyroid storm should not have lack of sweat or hypoactive bowel sounds as with an anticholinergic toxidrome. Patients with alcohol withdrawal or methamphetamine abuse will typically have other sequelae of chronic substance abuse. The only problem is that any of these processes can also precipitate a thyroid storm. A detailed history and examination is imperative to help differentiate these life threats from a thyroid storm.

With more subtle presentations of thyrotoxicosis, the differential diagnosis may include gastroenteritis, hepatitis, asthma exacerbation, anxiety disorder, other causes of high-output congestive heart failure, or pulmonary embolism to name a few. Apathetic hyperthyroidism or hyperthyroidism in the elderly may be confused for dementia, delirium, and other causes of unexplained weight loss.

ED EVALUATION

The diagnosis of thyrotoxicosis as well as thyroid storm is based on history and physical examination, identifying risk factors, and confirmatory TSH and free T_4 tests. Low TSH, less than 0.05–1 mU/L, with elevated T_4 confirms the diagnosis. TSH levels may be normal or elevated with elevated T_4 and T_3 levels in TSH-induced hyperthyroidism due to pituitary adenoma or partial resistance to the feedback loop. The severity of clinical manifestations may not

correlate with the degree of thyroid hormone elevation or TSH suppression.

In subclinical hyperthyroidism, the TSH may be borderline suppressed (>0.05 mU/L) with normal T_3 and T_4. These patients do not need emergent treatment in the emergency department and should follow up with their primary care physician on a routine basis. Follow-up testing for TSH and free T_4 is recommended in 6 to 12 months, especially in elderly patients who are at increased risk of cardiovascular disease, atrial fibrillation, unexplained extensive weight loss, and osteoporosis (13). The primary care physician would need to determine if the patient has a sustained TSH depression on repeat testing and make sure that there are not other nonthyroidal etiologies for depressed TSH (13).

Diagnostic evaluation of thyrotoxicosis depends on the severity of presentation. With less severe presentations such as anxiety, weight loss, or unexplained tachycardia, the evaluation should include electrolytes, complete blood count (CBC), thyroid function tests, and ECG. With more severe cases of thyrotoxicosis as in thyroid storm, a more aggressive approach to find the precipitating cause may include obtaining blood cultures, toxicologic screen, cardiac enzymes, chest x-ray, CT scan, and lumbar puncture (LP), if altered neurologic status and high fevers are present (8).

KEY TESTING

- CBC
- Chemistry panel
- Liver function tests
- Cardiac enzymes
- CPK
- Urinalysis
- ECG
- Core temperature
- Thyroid function tests
- Blood and urine culture
- Toxicologic screen

- Chest x-ray
- CT and LP, if clinically indicated

Other diagnostic tests may be used in follow-up with the endocrinologist to help determine the etiology of hyperthyroidism as well as guide in the treatment. Twenty-four hour radioiodine uptake and scan may be used to differentiate Graves disease with high radioactive uptake from most causes of thyroiditis that have low radioactive uptake. “Hot nodules” are nodules with increased radioactive uptake and they may also be seen with toxic adenoma and multinodular goiter. High radioactive uptake is associated with increased synthesis of new thyroid hormone as the etiology of hyperthyroidism, whereas low uptake is usually associated with little to no de novo synthesis. The pattern of uptake may also differentiate Graves disease from other causes of hyperthyroidism like toxic adenoma or toxic multinodular goiter.

ED MANAGEMENT

Treatment of thyroid storm involves several steps. The first step is to resuscitate the patient with supportive therapies including repletion of excessive fluid losses, rapid cooling of high fever, airway control if necessary, and rapid evaluation and treatment of any underlying precipitants. Dextrose containing IV solutions should also be used in addition to normal saline, supplemental multivitamins, and thiamine as there have been reported cases of Wernicke encephalopathy with severe thyrotoxicosis. Some of the signs and symptoms may not be corrected until definitive antithyroid medication is initiated. For example, rapid atrial fibrillation may be refractory to rate control or cardioversion until antithyroid medication is instituted (2).

The next steps include stopping synthesis of new hormone within the thyroid gland, halting release of stored thyroid hormone from the thyroid gland, preventing conversion of T_4 to T_3, and controlling the adrenergic symptoms associated with thyrotoxicosis (2).

With severe thyrotoxicosis or thyroid storm, a thionamide (methimazole or propylthiouracil [PTU]) should be given about an hour or two prior to giving iodine to block production of new thyroid hormone. Methimazole and PTU reduce the production of thyroid hormones by selectively inhibiting thyroid peroxidase (TPO). There are several risks in giving PTU including liver failure and agranulocytosis. PTU should be given as a second-line drug to methimazole except in first trimester of pregnancy or if the patient does not tolerate methimazole (12). Either agent may be used to treat thyroid storm. PTU has the additional advantage of inhibiting peripheral conversion of T_4 to T_3. On the other hand, the duration of action of methimazole is longer, and can therefore be given less frequently. In the United States, thionamides are typically given orally, but rectal preparations are also available. The powder form of methimazole can be mixed with normal saline and filtered to create an intravenous solution. IV forms of thionamides are available in Europe.

Various forms of iodine are then given to halt the release of thyroid hormone. Inorganic iodine (Lugol solution or saturated solution of potassium iodide [SSKI]) is used 1 hour after the administration of PTU or methimazole to block the release of preformed thyroid hormone. Large doses of iodine will reduce the organification of thyroglobulin. Blocking hormone synthesis must take place first prior to iodine therapy to ensure that the iodine cannot be used for further thyroid hormone production. Alternative therapy with lithium at a dose of 300 mg every 6 hours may be used to block release if the patient has an iodine allergy. Lithium dosage may be adjusted to maintain serum lithium of 0.8 to 1.2 mEq/L (8). The radiocontrast agent ipodate (Oragrafin) may also be used in this step as it inhibits peripheral T_4 conversion and blocks thyroid hormone release.

Corticosteroids are used to decrease peripheral conversion of T_4 and inhibit the release of thyroid hormone. Treatment of thyroid storm with corticosteroids may have the added affect of treating adrenal insufficiency which may occur concomitantly (2). The initial

dose of hydrocortisone is 300 mg followed by 100 mg every 8 hours during the first 24 to 36 hours. Thyroid storm has been reported to recur when steroids had been discontinued after initial clinical improvement (8).

β-Blockade is used to control the peripheral actions of thyrotoxicosis. β-Blockers not only correct tachycardia but also improve agitation, convulsions, psychotic behavior, diarrhea, fever, and excess sweating. Propanolol traditionally is the initial drug of choice as it blocks peripheral β-receptors as well as has the theoretical benefit of blocking the conversion of T_4 to T_3. A significant effect however is only seen at doses of 160 mg/d or greater (8). The dosing for propanolol is 60 to 80 mg every 4 hours. It can also be given intravenously every 10 minutes at a dose of 1 to 3 mg. IV esmolol may also be used in the potentially unstable patient because with its short half-life, it is easier to discontinue without prolonged adverse side effects. Longer-acting cardioselective β-blockers like atenolol or metoprolol may be used as well and have been shown to be just as effective as propanol with less frequent dosing despite not having the benefit of blocking peripheral conversion of T_4 to T_3 (8). β-Blockers are contraindicated with bronchospasm or severe congestive heart failure. If the cause of the heart failure is thought to be high output and due to the tachycardia from the thyrotoxicosis, a short-acting β-blocker may be the best choice. Diltiazem may also be used for rate control but it will not block the other peripheral β-receptor symptoms mentioned above (Table 208.7).

TABLE 208.7
Treatment of Thyroid Storm

(1) PTU 600 to 1,000 mg PO/PR then 200 to 250 mg every 4 hrs or
Methimazole 15 to 30 mg/d
(2) Inorganic iodine (1 hr after PTU)
Lugol solution 8 drops PO/PR every 6 hrs *or*
SSKI 5 drops PO/PR every 6 hrs
(3) Corticosteroids
Dexamethasone 2 mg IV every 6 hrs or
Hydrocortisone 300 mg IV then 100 mg every 8 hrs
(4) β-Blocker (If NO CHF)
Esmolol 250 to 500 µg/kg IV bolus then 50 to 100 µg/kg/min infusion or
Propanolol 60 to 80 mg PO every 4 hrs or
Propanolol 0.5 to 1 mg IV every 1 hr (infuse slowly)
(5) Supportive care
Acetaminophen, cooling blankets, IV fluids
(6) Treat the precipitating event
Broad-spectrum antibiotics if no source identified, treat CHF, MI, stroke, pulmonary emboli, etc.

Along with providing specific treatment for thyroid storm, it is also important to provide supportive care for the clinical manifestations as well as identify and treat the precipitating cause. If no infectious source is identified in the unstable patient, broad-spectrum antibiotics should be administered until a source is identified. When clinical deterioration occurs in thyroid storm, despite the use of all of these medications, removal of thyroid hormone with plasmapheresis, charcoal hemoperfusion, resin hemoperfusion, and plasma exchange has been found to be effective (2).

Therapy for uncomplicated cases of thyrotoxicosis in the emergency department usually consists of initiation of a β-blocker for symptomatic relief. Patient may be given a first dose intravenously or orally depending on the severity of clinical presentation and discharged on an oral regimen of either propanolol or a cardioselective long-acting β-blocker. A thionamide may be started if there is clinical suspicion for Graves disease as well as in cases of toxic adenoma and multinodular goiter, where overproduction of thyroid hormone is the suspected cause of the patient's symptoms. For the reasons mentioned above, methimazole

is the preferred first-line drug except in first trimester of pregnancy. Methimazole is started at 15 to 30 mg/d with maintenance doses of 5 to 10 mg/d. PTU is initiated at a dose of 100 mg every 8 hours and can be reduced to 50 mg two to three times a day once the euthyroid state is reached.

Although definitive treatment is not started in the emergency department, it is important to be able to communicate the potential treatment options to the patient. With Graves disease there are three definitive treatment options: prolonged antithyroid medication with thionamides, iodine therapy, and partial or total thyroidectomy.

The goal of RAI is to create a euthyroid state, but up to 10% may still be hyperthyroid after treatment. Up to 20% may become hypothyroid and have a 3% to5% increased risk of developing hypothyroidism each year. Thyroidectomy is reserved for patients with a severe allergy to thionamides, pregnant patients, or patients suffering from severe compressive symptoms from a large goiter. Antithyroid treatment is the preferred first-line method of treatment during pregnancy.

There has been some success with prolonged thionamide treatment. Up to 40% of patients receiving thionamides will undergo remission after 6 to 18 months of therapy. A fourth treatment option is referred to as block and replace. Patients who are difficult to stabilize are put on a dose of antithyroid medication to block thyroid function, and then given thyroid replacement hormone to normalize thyroid function. It is thought that this option may create more stable thyroid levels and make antithyroid treatment more tolerable.

Management of thyroiditis is typically less complicated and the symptoms are usually transient. With subacute thyroiditis antithyroid medication is not necessary because symptoms are based on release of preformed thyroid hormone, not overproduction. This condition is usually treated with nonsteroidal medication or a prednisone taper. β-Blockers may be needed for symptomatic relief. Other more rare forms of thyroiditis such as medication induced or infectious require treatment of the underlying cause.

Common Pitfalls

- Not recognizing thyrotoxicosis in an elderly patient with apathetic hyperthyroidism.
- Administration of iodinated contrast to a thyrotoxic patient without recognizing the risk of developing thyroid storm.
- Administration of iodinated contrast to a patient who is in the process of workup for thyroid disease, therefore delaying future diagnostic and treatment options.
- Diagnosing and treating thyroid storm without searching for and treating the precipitating event.
- Failure to consider thyroid storm in a patient that presents with hyperadrenergic signs and symptoms (i.e., tachycardia, high fever, tachypnea, agitation).
- Using long-acting β-blockers rather than short-acting β-blockers in an unstable patient presenting with signs of thyroid storm.

CRITICAL INTERVENTIONS

- In an ill patient with a history of thyrotoxicosis or a goiter, suspect and treat thyroid storm early.
- In the treatment of thyroid storm, administer a thionamide 1 hour before inorganic iodine.
- Administer the short-acting agent esmolol in unstable patients or patients with signs of congestive heart failure.
- Early administration of broad-spectrum antibiotics in a patient with decompensated severe thyrotoxicosis even if a definitive infectious source has not yet been identified.

HYPOTHYROIDISM

Hypothyroidism is one of the most common endocrine disorders. It is more common in women and the elderly. The incidence is about 0.5% in the United States and increases to 2% to 3% in the elderly. Primary hypothyroidism occurs as a result of undersecretion of thyroid hormone from the thyroid gland.

Secondary hypothyroidism may occur as a result of damage or disease of the pituitary or hypothalamus. Secondary hypothyroidism may be masked by other endocrine deficiencies such as hypogonadism and adrenal insufficiency (14). Almost 95% of hypothyroidism is primary, whereas secondary hypothyroidism is very rare.

Causes of Primary Hypothyroidism

Iodine deficiency is the most common cause of hypothyroidism worldwide. Chronic autoimmune (Hashimoto disease) thyroiditis, which is mentioned earlier in the chapter, is the most common cause in iodine-sufficient areas (15). It is associated with antibodies against TPO and/or thyroglobulin as well as lymphocytic infiltration of the gland. As discussed above, Hashimoto disease may have transient hyperthyroid phases but the typical course is slow destruction of the gland that eventually results in hypothyroidism. There can often be alternating periods of hyperthyroid and hypothyroid symptoms, which is characteristic of Hashimoto disease.

Another common cause of hypothyroidism is a total thyroidectomy with clinical signs typically developing within 2 to 4 weeks. The majority of patients with subtotal thyroidectomy for Graves disease are typically euthyroid after 1 year, but approximately 1% becomes hypothyroid each year after their surgery (16).

Radiation and radioactive iodine are both associated with hypothyroidism. After I-131 treatment, the majority of patients will be hypothyroid after 1 year and the remaining patients at a rate of about 2% per year (16). Radiation for other head and neck cancers as well as exposure to nuclear accidents has an increased risk of hypothyroidism.

Medications have multiple effects that can lead to a hypothyroid state. Drugs such as lithium, amiodarone, interferon, and interleukin-2 have been associated with hypothyroidism. Cholestyramine, proton pump inhibitors, calcium carbonate,

phosphate binders, and ferrous sulfate can decrease absorption in hypothyroid patients taking T_4. The end result may be a patient on thyroid placement with persistent symptoms of hypothyroidism despite adequate thyroxine dosing (15). A more extensive list of all the causes of hypothyroidism is given in Table 208.8 (16).

TABLE 208.8
Causes of Hypothyroidism

Autoimmune thyroiditis (Hashimoto)
Subacute, silent or postpartum thyroiditis
Systemic illness
Neonatal
- Thyroid agenesis
- Genetic disorders affecting thyroid hormone synthesis
- Transplacental passage of TSH receptor blocking antibody

Radioablation with I^{131} for hyperthyroidism and thyroidectomy
Iodine deficiency or excess
Radiation exposure
Medications
- Lithium
- Amiodarone
- Iodine deficiency or excess or iodinated contrast
- Sulfonamides
- Phencyclidine
- Antithyroid medications

Causes of secondary hypothyroidism:
Infiltrative processes (both primary and secondary)
- Neoplasia (lymphoma)
- hemochromatosis
- Sarcoidosis
- Tuberculosis
- Reidel thyroiditis (fibrous)
- Histiocytosis
- Amyloidosis
- Scleroderma

Tumors, infarcts, or trauma
Sheehan syndrome (postpartum pituitary necrosis)
Lymphocytic hypophysitis
Infection and medication (14,15)

CLINICAL PRESENTATION

Hypothyroidism may affect all organ systems. Signs and symptoms depend on the degree of thyroid deficiency as well as whether the etiology is primary or secondary. Generalized fatigue, cold intolerance, and weight gain are common. Patients typically present with gradual onset of symptoms over months to years. The spectrum of clinical presentations ranges from subclinical hypothyroidism

with no symptoms to severely decompensated hypothyroidism. Because the symptoms are usually vague, they often mimic signs and symptoms of other euthyroid illness (15). As in hyperthyroidism, there should be detailed attention to vital signs as well as general appearance. Patients may be lethargic with slow movement and slow speech. Thick and hoarse speech is thought to be due to myxedema of the tongue and larynx. Generalized muscle stiffness is present especially when exposed to cold (17).

Decreased cardiac output can lead to narrowed pulse pressure with cool pale extremities. Alterations in the cardiovascular system manifest as ECG changes which include sinus bradycardia, low amplitude, and flattening or inverted T waves. Echocardiography may demonstrate small pericardial effusions as well as findings of left ventricular diastolic dysfunction (17). Distant heart sounds may be appreciated on examination and enlarged cardiac silhouette can be seen on chest x-ray. Many of these clinical findings may mimic congestive heart failure. In patients with no underlying heart disease, treatment with thyroxine will reverse most if not all of these changes (14).

Respiratory symptoms may include shortness of breath and decreased exercise capacity. Hypoventilation can occur with more severe hypothyroidism. Rarely, pleural effusions may be appreciated on chest x-ray. Reversible obstructive sleep apnea is not uncommon.

Constipation is the most common gastrointestinal sign with hypothyroidism. Ileus may be confused with bowel obstruction. Decreased taste sensation has also been reported. Other autoimmune gastrointestinal-related diseases such as pernicious anemia from antiparietal antibodies and celiac disease are more prevalent especially in those patients with hypothyroidism due to autoimmune thyroiditis (14,17).

Neurologic manifestations may include mild symptoms such as numbness and tingling in extremities and carpal tunnel syndrome from glycosaminoglycan deposits on the median nerve (17). Deep tendon reflexes may be delayed in the relaxation phase. Some of the more severe neurologic symptoms include problems with memory, night blindness, hearing loss, dementia, stupor, syncope, and rarely

seizures in more severe cases. Evaluation of a new paranoia or depression should include thyroid functions tests (TFTs) looking for hypothyroidism (14,17).

Multiple cutaneous manifestations are found in patients with hypothyroidism. Hylauronic acid accumulates in soft tissue, which leads to mucinous edema that is responsible for the thickened features, pretibial edema, and puffy appearance, which is referred to as myxedema. Decreased production by sweat glands is associated with hyperkeratosis and ruff dry skin. Growth of hair is slowed and nails are brittle. Wounds also tend to heal slowly (17).

Metabolic abnormalities include hyponatremia, hypoglycemia, reversible increases in serum creatinine, increased triglycerides and free fatty acids, and elevation in creatine kinase. Delay in secretion of water due to decreased perfusion of the kidney may contribute to hyponatremia and decreased renal function (8).

Changes in sexual and reproductive function in women may include amenorrhea or abnormal menses. Alteration in cycles may contribute to decreased fertility. In pregnancy, there is also an increased risk of abortion in women with hypothyroidism. Galactorhea may develop from overstimulation of the hypothalmus by TRH. Other findings due to undersecretion of the pituitary gland may also be seen in secondary hypothyroidism. In men, decreased libido, erectile dysfunction, and altered sperm morphology may contribute to infertility as well. This is partially reversible with treatment (17).

Table 208.9 summarizes the more common signs and symptoms of hypothyroidism.

TABLE 208.9
Signs and Symptoms of Hypothyroidism

Appearance

- Puffy and pale facies
- Dry, brittle hair
- Sparse eyebrows
- Dry, cool skin
- Thickened and brittle nails
- Myxedema—fluid infiltration of tissues

Energy and nutrient metabolism

- Cold intolerance
- Weight gain
- Fatigue

Nervous system

- Headache
- Paraesthesias (including carpal tunnel syndrome)
- Cerebellar ataxia
- Delayed relaxation of deep tendon reflexes

Cognitive/psychiatric

- Reduced attention span
- Memory deficits
- Depression

Cardiovascular

- Bradycardia
- Diastolic hypertension
- Pericardial effusion
- Decreased exercise tolerance

Musculoskeletal

- Myalgias
- Arthralgias

Gastrointestinal

- Anorexia
- Constipation

Reproductive system

- Irregular or heavy menses
- Infertility

Additional investigations

- Hypercholesterolemia (statin therapy in hypothyroid patients increases risk of rhabdomyolysis)
- Raised creatine kinase
- Hyponatremia
- Mild anemia (15)

ED EVALUATION AND MANAGEMENT

Diagnosis of hypothyroidism in the emergency department should consist of screening with TSH and free T_4 based on the clinical clues listed above. Elevated TSH (>10 mU/L) with low T_4 should indicate the need for treatment with levothyroxine. Low TSH and low T_3 and T_4 suggest secondary hypothyroidism. Low TSH can also occur when the adrenal gland is stressed as well. If there is suspicion for secondary hypothyroidism, further testing should include prolactin level, FSH, LH, ACTH, and cortisol levels. If there is a high index of suspicion for secondary hypothyroidism, adrenal function must be tested prior to initiating thyroid replacement therapy. Starting patients on thyroid replacement with a cortisol deficiency prior to starting glucocorticoids could precipitate an Addisonian or adrenal crisis.

An elevated TSH with a normal free T_4 is referred to as subclinical hypothyroidism. This is detected in 4% to 8% of the general population and in up to 15% to 18% of women aged more than 60 years. The benefit of treating subclinical hypothyroidism is somewhat controversial. The potential risks of not initiating therapy include progression to overt hypothyroidism, cardiovascular effects, worsening lipid profiles, and neuorpsychiatric effects (15,18). This is especially true when treating subclinical hypothyroidism in pregnancy as this could potentially prevent long-term psychomotor and auditory development in the neonate (13).

A recent Cochrane review found that in nonpregnant patients, thyroxine versus no treatment for subclinical hypothyroidism did not affect overall survival but did improve markers for cardiovascular disease such as lipid profile (15,18). Most of the literature still recommends treatment however if patients have a TSH over 10 with a normal free T_4. No treatment is indicated with TSH between 5 and 10 mU/L with a normal free T_4 unless patients exhibit signs of hypothyroidism. In this case, the patient may be given a 3- to 6-month trial with synthroid to see if symptoms improve. All other patients can be referred to their primary

physician for risk stratification to determine if treatment is needed (13,16,19).

The recommended approach to treating hypothyroidism is to titrate thyroxine therapy against the TSH concentration while assessing clinical response to treatment. It is important to note especially in the emergency department setting that repeat TSH levels should not be obtained until about 3 to 4 weeks after therapy is initiated. Checking the levels too early can lead to unnecessarily increasing the dosage of thyroid replacement. Furthermore, it also takes patients several weeks for their symptoms to improve after starting treatment (13).

The recommended starting dose for the majority of patients is 50 to 100 μg of thyroxine. Higher doses may be indicated in patients post-thyroidectomy. Doses should be increased in 25 to 50 μg increments with the TSH repeated every 4 to 6 weeks after each change. Most patients will become clinically euthyroid in the range of 75 to 150 μg/d (1.6 μg/kg on average based on ideal body weight). In elderly patients, especially those with ischemic heart disease, the initial dosage should be 25 μg with increases of 25 μg rather than 50-μg increments (13).

During pregnancy, there is an increased need for thyroxine especially in women with pre-existing hypothyroidism. Furthermore, absorption of thyroxine may also be decreased with pregnancy requiring increased dosing. Hypothyroid pregnant patients receiving thyroxine therapy should get an additional 25 to 50 μg per day to maintain normal serum TSH levels. About 2 to 4 weeks after delivery, the dosage can usually be decreased back to prepregnancy levels depending on the TSH level (13).

Untreated hypothyroidism in pregnancy has been associated with several adverse maternal and fetal outcomes including early miscarriage, intrauterine fetal demise, placental abruption, gestational hypertension, postpartum hemorrhage, gestational diabetes, and delayed neurologic development as well as lower IQ in the neonate (14).

Several preparations of levothyroxine are available including synthroid, levothyroid, unithyroid, levoxyl, and generic. They all

appear to be equivalent in terms of thyroid replacement (20). Some patients have reported having more improvement of symptoms with preparations that combine T_4 and T_3 or just use T_3 alone. These preparations include the products triiodothyronine (Cytomel) or desiccated thyroid (Armour). Several studies have actually shown subjective improvement of symptoms with combined therapy versus synthroid alone (21). Larger studies have not confirmed the benefit of combined therapy however.

Common Pitfalls

- Failure to consider hypothyroidism in elderly patients with cognitive deficits or patients with an unexplained pleural effusion or anemia.
- Failure to consider the effect of many commonly prescribed drugs and pregnancy on thyroid function.
- Expecting the rapid return of the TSH level to normal in a patient recently started on hormone replacement for hypothyroidism.

MYXEDEMA COMA

Myxedema coma is defined as severe hypothyroidism presenting as decreased mental status, hypothermia, and other signs and symptoms of a decreased metabolic rate. It is extremely rare with an incidence of 0.22 per million per year. It is most common in elderly women with long-standing hypothyroidism and other comorbidities (8).

CLINICAL PRESENTATION

Myxedema coma most commonly occurs with severe infection, sepsis, myocardial infarction, cold exposure, or administration of sedatives, antidepressants, or opioids (Table 208.10).

TABLE 208.10
Precipitants of Myxedema Coma

Infection
Trauma, burns
Cerebral vascular accident
Congestive heart disease
Gastrointestinal bleeding
Lung disease/CO_2 retention
Hypothermia
Hypoglycemia
Untreated hypothyroidism
Discontinuation of thyroid replacement
Medications
- Drug overdose
- Diuretics, amiodarone, β-blockers
- Sedatives, lithium, phenytoin

Physical findings include all those mentioned in Clinical Presentation of hypothyroidism, with bradycardia, macroglossia, hoarseness, cachexia, hypoventilation, severe hypothermia (often profound to 80°F [26.7°C]), and decreased level of consciousness. Hypotension may exist in up to 50% of cases from decreased cardiac contractility. Coma is misleading as mental status changes may range from slowing of speech to unconsciousness. Seizures may occur in up to 25% of these patients and are often due to hypoglycemia or hyponatremia. Severe tongue and laryngeal swelling may create a difficult airway. Puffiness of the hands and face with nonpitting edema are also common signs of myxedema (Fig. 208.2). Myxedema however does not need to be present to have severely decompensated hypothyroidism (8).

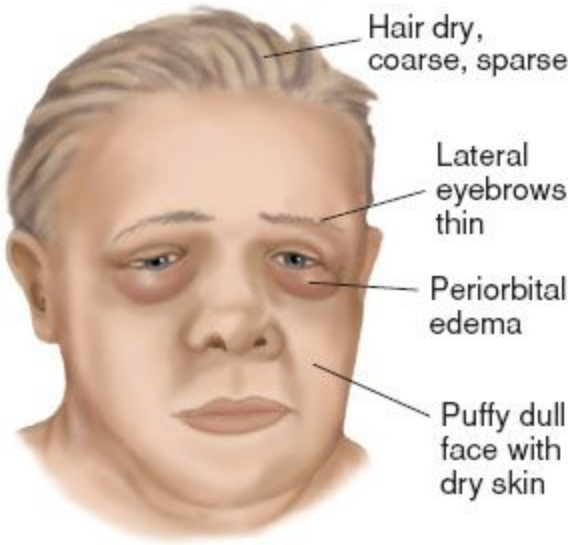

FIGURE 208.2 Myxedema: The patient with severe hypothyroidism (myxedema) has a dull, puffy facies. The edema, often particularly pronounced around the eyes, does not pit with pressure. The hair and eyebrows are dry, coarse, and thinned. The skin is dry. (From Bickley LS Szilagyi P. *Bates' Guide to Physical Examination and History Taking*, 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003.)

DIFFERENTIAL DIAGNOSIS

With a diverse array of symptoms including hypotension, hypothermia, and altered mental status, the differential diagnosis for myxedema coma is broad. In addition, other findings associated with panhypopituitarism and adrenal insufficiency with secondary hypothyroidism may cloud the picture even more. The differential diagnosis of myxedema includes sepsis, meningitis, cold exposure, stroke, SIADH and seizure disorder, intracranial hemorrhage, prolonged hypoglycemic reaction, ingestion of sedative hypnotics, gastrointestinal bleed, as well as numerous other metabolic disorders. The presentation may also be mistaken for acute heart failure with the presence of increased heart size, peripheral edema, pleural effusions, and hypotension. Furthermore, any of these illnesses may occur concomitantly with myxedema and may actually be the precipitant.

ED EVALUATION

Laboratory testing should include TSH, free T_4, urine and blood cultures, electrolytes with glucose, coagulation panel, cortisol level, ECG, and cardiac enzymes. Imaging should include a chest x-ray and head CT when indicated. A LP should be performed if suspicious for meningitis. Severe hyponatremia may contribute to the comatose state. Renal failure with rhabdomyolysis is not uncommon. In contrast to mild hypothyroidism where thrombosis is more likely, severe hypothyroidism is associated with a higher risk of bleeding due to acquired von Willebrand syndrome (type 1) and decreases in factors V, VII, VIII, IX, and X (8). Patients with myxedema coma may have elevated opening pressures in the CSF as well as elevated CSF protein (8).

ED MANAGEMENT

Myxedema coma should be treated very aggressively as the mortality is 30% to 40%. Patients with the greatest risk are elderly patients as well as those with cardiac complications, altered level of consciousness, hypothermia, and sepsis. Table 208.11 shows an algorithm for the treatment of myxedema coma.

TABLE 208.11
Treatment of Myxedema Coma

1. Levothyroxine 200 to 500 µg IV followed by 75 to 100 IV/PO µg per day
2. IV fluids, pressors, and mechanical ventilation as needed; caution with pressors
3. Passive rewarming. Try to avoid active rewarming to avoid excess vasodilation
4. Hydrocortisone 100 mg IV or dexamethasone 6 mg IV an hour prior to thyroxine
5. Treat any precipitants with special attention to a potential infectious etiology

Treatment should consist of thyroid replacement, supportive measures, and recognizing and treating the precipitating cause. Patients must be treated with stress dose steroids prior to thyroid replacement until concomitant adrenal insufficiency has been ruled

out. Hydrocortisone 100 mg should be given intravenously every 8 hours. Initial treatment should involve airway management as the patient's comatose state may be worsened by hypoventilation and severe respiratory acidosis. Mechanical ventilation may be required for the first 36 to 48 hours and in some cases up to 2 to 3 weeks. Patients should not be extubated until they are fully awake as hypoxia may persist even after the respiratory acidosis has been corrected (8).

The emergency physician is sometimes hesitant to give IV thyroxine especially if thyroid function testing results are not yet available or the patient has underlying cardiac disease. Although there may be some risk of precipitating a myocardial infarction, these risks have to be weighed against the benefits of treating the myxedema coma. One study looked at administration of 500 μg of thyroxine as an IV loading dose followed by 100 μg daily and found this regimen to have a lower mortality than with 100 μg daily without a loading dose (22). There will be no immediate signs of clinical improvement after initial administration of thyroxine, as it must be converted to the more active form T_3 first. Initial effects may not be seen for over 24 hours.

Administration of T_3 alone is not considered safe. High T_3 concentrations during treatment have been associated with increased mortality (16,21). It is controversial as to whether T_3 should be administered with T_4 to patients with severely decompensated hypothyroidism. Patients with myxedema have decreased conversion of T_4 to T_3, which is thought to be a protective mechanism against the more biologically active T_3. Although most clinicians treat with thyroxine alone due to a better safety profile (23), combination therapy of T_4 and T_3 has been reported. Instead of administering 300 to 500 mg of T_4, the T_4 dose is reduced to 200 to 300 mg and is given with an initial bolus of 10 mg of T_3. An additional dose of 100 mg T_4 is given 24 hours later and T_3 is continued at 10 mg every 8 to 12 hours until the patient is conscious and able to take maintenance T_4.

Additional supportive measures include treating the underlying cause with early broad-spectrum antibiotics until a source is identified, correcting electrolyte abnormalities, supporting blood pressure, and correcting hypothermia. Passive rewarming is preferred over active rewarming, as there may be an increased risk of vasodilation and worsening hypotension. Hypotension is often corrected with thyroid hormone replacement. If fluids are indicated, dilute preparations should be avoided to avoid worsening hyponatremia.

Severe symptomatic hyponatremia associated with seizures or altered mental status may require administration of small amounts of hypertonic saline. A vasopressin antagonist, conivaptan, has also been used to treat hypothyroid patients with hyponatremia. Conivaptan is thought to work due to high vasopressin levels seen with hyponatremia in the setting of severe hypothyroidism (8).

Vasopressors should be used but with caution as there is an increased risk of an ischemic event in a patient with a long-standing depressed metabolic state. Steroids, as mentioned above, may also be of benefit if hypotension is due to adrenal insufficiency (8). Additional dextrose may be added to intravenous fluids with persistent hypoglycemia.

In addition to treating potential underlying infections, other precipitating events must be addressed as well including myocardial infarction, stroke, congestive heart failure, or any other potential precipitating events as well as a thorough review of medications and dosing.

DISPOSITION

Patients with myxedema coma typically require prolonged ICU stays. Mortality ranges from 15% to 30%. Factors that increase mortality include coma, advanced age, core temperature $<93^{\circ}F$, bradycardia <44 beats/min, hypotension, and concomitant sepsis or myocardial infarction (24).

Common Pitfalls

- Failure to consider the diagnosis of myxedema coma in a patient with altered mental status and a history of hypothyroidism.
- Failure to administer hydrocortisone or dexamethasone prior to giving thyroxine in order to avoid precipitating an adrenal crisis.
- Use of active rewarming that may precipitate hypotension.
- Failure to search for and treat precipitating events, especially infection.

CRITICAL INTERVENTIONS

- IV levothyroxine should be administered prior to thyroid test results in patients with suspected myxedema coma.
- Vasopressors should be used with caution in the treatment of myxedema coma.
- Passive rewarming should be instituted in myxedema patients, because active rewarming may precipitate hypotension.

THYROID NODULES

Thyroid nodules are estimated to be present in about 50% of the population based on postmortem and ultrasound studies. Only about 5% of nodules are cancerous. Typically, thyroid nodules do not require emergency department ancillary testing except for thyroid function tests if clinically indicated. Other diagnoses should be considered in evaluating thyroid nodules, including branchial cleft cyst, thyroglossal duct cyst, neck abscess, lymphoma, reactive lymphadenopathy, and Hodgkin disease.

In nontoxic patients, where there is low clinical suspicion for overt hyperthyroidism, hypothyroidism, acute infection, or airway compromise, outpatient workup is all that is required. Even though these tests are not performed in the emergency department, it is important to understand the diagnostic process for the evaluation of a thyroid nodule so as to communicate better with your consultant and give your patients reassurance as well as a more informative treatment plan. If a patient presents with clinical findings of a nontoxic goiter, thyroid asymmetry, or palpable nodules, follow-up thyroid ultrasound should be arranged. Fine-needle aspiration

biopsy of a goiter is indicated if there is a rapid growth, pain, as well as suspicious findings on ultrasound.

Patients with thyroid nodules associated with an initial low TSH and elevated T_4 require an outpatient thyroid scan rather than a thyroid ultrasound. Thyroid nodules that absorb radioiodine are referred to as “hot nodules” and are typically not cancerous. Nodules that do not take up radioiodine are referred to “cold” nodules and have a 5% chance of being cancerous and require further workup.

CHAPTER 209

Adrenal and Pituitary Disorders

Adam G. Field

The adrenal gland is made up of two distinct glands, the cortex and the medulla. The adrenal cortex is made up of three zones. The outer zone, which is referred to as the zona glomerulosa, secretes the mineralocorticoid aldosterone which maintains salt balance and regulates blood pressure. The intermediate zone, the fasciculata, secretes cortisol, which is a key factor in the body's response to stress. More specifically, it helps to regulate immune function, vascular tone, and metabolism. The inner zone, the reticularis, secretes androgens (sex hormones and their precursors). The adrenal medulla produces the catecholamines epinephrine and norepinephrine. Important adrenal disorders that need to be identified in the emergency department (ED) include the following: inadequate cortisol production (adrenal insufficiency), excess cortisol production (Cushing disease), and excess catecholamine release (pheochromocytoma) (1).

ADRENAL INSUFFICIENCY

Primary adrenal insufficiency or Addison disease is the result of direct destruction of the adrenal cortex which leads to decreased secretion of cortisol, aldosterone, and androgens. Secondary or tertiary adrenal insufficiency arises from failure of the hypothalamic–pituitary axis (HPA) to produce sufficient adrenocorticotropic hormone (ACTH) or corticotropin-releasing

hormone (CRH), which stimulates the adrenal glands to produce cortisol. With secondary adrenal insufficiency, the renin–angiotensin–aldosterone system remains intact. Aldosterone primarily stimulates the kidney to reabsorb sodium and excrete potassium and hydrogen ions. Patients with secondary adrenal insufficiency, therefore, do not have the salt wasting, hyperkalemia, and hypovolemia seen in primary adrenal insufficiency and less often present with hypotension (2). Patients with secondary adrenal insufficiency therefore only require cortisol replacement, whereas patients with primary adrenal insufficiency need both glucocorticoid and mineralocorticoid replacement.

Androgen replacement is typically only needed in preadolescent females for proper development of secondary sex characteristics as well as women with signs of androgen deficiency such as dry itchy skin, decreased libido, and mood instability. The majority of androgens in males are produced in the testes, not in the adrenal gland.

Primary adrenal insufficiency is an uncommon disorder, affecting approximately 100 persons per million (2). When Thomas Addison first described the disease, bilateral adrenal destruction by tuberculosis was the most common cause. Now tuberculosis accounts for $<10\%$ of cases in Western countries, whereas autoimmune disease is responsible for 70% to 90%. The remaining etiologies include other infectious diseases, replacement by metastatic cancer, adrenal hemorrhage or infarction, and drugs (Table 209.1). Autoimmune adrenalitis or "idiopathic" primary adrenal insufficiency is a process involving both humoral and cellular immune mechanisms that are directed at the adrenal cortex. This process is often associated with autoimmune destruction of other endocrine glands and is part of autoimmune polyendocrine syndrome (APS) type I or type II (3). In type I APS, hypoparathyroidism or chronic mucocutaneous candidiasis often precedes the onset of adrenal insufficiency. Type II APS is often associated with autoimmune thyroid disease and type I diabetes mellitus. Hypogonadism, pernicious anemia, vitiligo, and other autoimmune processes may be associated with both types of APS.

Primary adrenal insufficiency associated with APS is more common in females (70%); isolated autoimmune adrenalitis is more common in males in the first two decades of life, and later in life occurs predominantly in females.

TABLE 209.1
Causes of Primary Adrenal Failure

Autoimmune disease: associated with autoimmune polyglandular syndromes
Metastatic cancer: lung, breast, colon, kidney, pancreas, leukemia
Infection: tuberculosis, fungal, viral (CMV, HIV/AIDS), bacteremia, sepsis (Waterhouse–Friderichsen syndrome)
Infiltrative diseases: sarcoidosis, amyloidosis, hemochromatosis
Hemorrhage: anticoagulant therapy, abdominal trauma, post-liver transplantation
Adrenal infarction: hypercoagulable states, adrenal vein thrombosis, arteritis
Drugs: ketoconazole, etomidate, high-dose fluconazole, rifampin, aminoglutethimide, metyrapone, mitotane
Miscellaneous causes: adrenalectomy, adrenomyeloneuropathy, congenital adrenal hyperplasia

Adapted from Kruse JA, Carlson-Fink MP. *Manual of Critical Care.* 1st ed. Philadelphia, PA: WB Saunders; 2003.

With the exception of autoimmune adrenalitis and tuberculosis, other causes of primary adrenal insufficiency are rare (see Table 209.1). Adrenal metastasis is often found on autopsy but rarely causes adrenal insufficiency, as more than 90% of the cortex must be involved to become symptomatic (4). Primary acute adrenal insufficiency may occur as a result of infarction caused by hemorrhage or adrenal vein thrombosis. Adrenal hemorrhage can be associated with sepsis, coagulopathy, thromboembolic disease, hypercoagulable states, trauma, and (rarely) after liver transplantation. When adrenal hemorrhage is associated with meningococcemia, it is referred to as *Waterhouse–Friderichsen syndrome.* It can occur at any age but is somewhat more common in children. Prompt diagnosis and treatment with the appropriate antibiotics is imperative or the patient may die within hours to days. Other pathogens associated with this syndrome include *Pseudomonas*

aeruginosa, Escherichia coli, Streptococcus pneumoniae, Haemophilus influenzae, Neisseria gonorrhoeae, and *Staphylococcus aureus* (5).

The most common cause of secondary adrenal insufficiency (inadequate pituitary ACTH reserve) is suppression of the HPA axis by exogenous glucocorticoids. The likelihood of suppression is related to the dose of glucocorticoids and the duration of treatment. Suppression is unlikely with doses equivalent to <5 mg/d of prednisone and duration of <2 weeks (4).

Depending on the dose and duration of therapy, it may require several months to 1 year after withdrawal of glucocorticoids before the HPA axis again functions normally. Adrenal suppression has also been reported infrequently with prolonged inhaled and topical corticosteroid use (4).

Secondary adrenal insufficiency is otherwise caused by disorders that destroy or compromise pituitary or hypothalamic integrity, such as pituitary or parasellar tumors (prolactinoma, acromegaly, meningioma, craniopharyngioma); hypothalamic tumors; head trauma; infarction (pituitary apoplexy); cranial radiation; infiltrative or inflammatory processes; and hemorrhage (Sheehan syndrome). With the exception of trauma, infarction, and hemorrhage, pituitary and hypothalamic disease tends to result in gradual rather than sudden loss of function.

Adrenal insufficiency is seen in patients with human immunodeficiency virus (HIV) and AIDS at a rate higher than in the general population. Patients with HIV can have both primary and secondary adrenal insufficiencies. Patients with AIDS often have elevated basal serum cortisol levels but have a decreased adrenal reserve as measured by serum cortisol response to prolonged ACTH stimulation. The diagnosis is often overlooked because the vague symptoms are attributed to the patient's medications or to the virus. It appears that many factors contribute to adrenal insufficiency in this population, including HIV itself, opportunistic infections, malignancy, and medications frequently used by HIV-infected patients (6).

Adrenalitis is caused by cytomegalovirus, atypical mycobacterium, or disseminated fungal infection and infiltration

from Kaposi sarcoma. Some drugs used to treat opportunistic infections in AIDS (e.g., ketoconazole) inhibit cortisol synthesis (4,6). Unlike ketoconazole, fluconazole in standard doses is not thought to interfere with cortisol production, although in higher doses adrenal insufficiency has been reported as well (6). Rifampin, which increases cortisol metabolism, may precipitate adrenal crisis in patients with subclinical adrenal insufficiency. Concomitant use of these as well as other drugs that affect cortisol metabolism may require dose adjustment of steroids in patients with adrenal insufficiency. Steroids used for the treatment of *Pneumocystis carinii* pneumonia or in combination with other HIV therapy may lead to secondary adrenal insufficiency. Cases of Cushing syndrome have been described with the concomitant use of fluticasone and ritonavir, as well as severe adrenal insufficiency with discontinuation of fluticasone. Rare case reports of interactions between ritonavir and budesonide or ritonavir and intra-articular triamcinolone have also been reported. Long-term steroid replacement is usually necessary until the HPA recovers (6).

Megestrol acetate, an appetite stimulant used in patients with weight loss related to cancer or AIDS, has also been associated with secondary adrenal insufficiency (6). It was also recently reported that infants of human immunodeficiency virus 1 (HIV-1) infected mothers who were treated before and after birth with the protease inhibitor lopinavir–ritonavir were more likely to experience adrenal dysfunction, including life-threatening adrenal insufficiency in premature infants, compared with a zidovudine-based regimen (7).

Adrenal insufficiency has been observed in 30% to 70% of patients with septic shock. There has been controversy as to whether administration of intravenous steroids is helpful or harmful in the setting of septic shock. In the Surviving Sepsis Campaign, it was concluded that patients with fluid and vasopressor refractive shock should be presumed to have adrenal insufficiency and treated as such, pending the results of confirmatory laboratory data (8).

Etomidate, which is an excellent induction agent for critically ill hypotensive patients, can also have adverse effects on the HPA axis, leading to decreased cortisol production and adrenal insufficiency.

Recent literature has argued that the excellent safety profile of single-bolus etomidate may outweigh the often transient effects of adrenal insufficiency. A large, prospective, randomized control trial of single-dose etomidate (0.3 mg/kg) versus midazolam (0.1 mg/kg) used for rapid sequence intubation of patients meeting sepsis criteria demonstrated no difference in mean hospital stay, ventilator days, or hospital mortality. Prolonged administration of etomidate in the intensive care setting is not recommended, however, because of the potential for adrenal suppression (9).

CLINICAL PRESENTATION

The clinical features of adrenal insufficiency are related to the rate of onset and severity of adrenal deficiency. In most cases, the disease has a gradual onset, and a diagnosis is made only when the patient presents with an acute crisis from an inadequate rise in cortisol secretion during a physiologic stress (10). Adrenal crisis can also occur in patients who are receiving physiologic doses of glucocorticoid if their mineralocorticoid requirements are not met. Acute stressors include, but are not limited to, severe infection, sepsis, alcohol withdrawal, trauma, surgery, myocardial infarction, and other toxic metabolic disease processes. In newborns, traumatic delivery or prolonged and difficult labor may precipitate adrenal crisis (11).

Acute adrenal insufficiency or “addisonian” crisis is a medical emergency that typically presents with altered mental status and hypotension out of proportion to the severity of concurrent illness and may not correct as readily as expected with pressors and fluids. Gastrointestinal symptoms including anorexia, nausea, vomiting, diarrhea, and abdominal pain are the most common initial presenting symptoms. The abdominal pain may suggest an acute abdomen. Unexplained fevers may also occur. Other associated autoimmune endocrine deficiencies may present concomitantly, such as hypothyroidism or gonadal failure.

The presentation of chronic adrenal insufficiency is more subtle, with symptoms of weakness, fatigue, weight loss, intermittent

vomiting, diarrhea or constipation, muscle cramps, arthralgias, and postural hypotension. Low-grade fever and salt craving may also be present. The classic physical finding that differentiates primary from secondary adrenal failure is skin hyperpigmentation or the “suntan that doesn’t fade.” With both acute and chronic primary adrenal insufficiency, pigmentation is seen in sun-exposed areas and in recent scars, palmar creases, nipples, axillae, mucous membranes (vaginal, buccal, and anal), nail beds, and pressure points. This skin manifestation is felt to be due to overproduction of ACTH, which stimulates increased production of melanin.

Patients with secondary adrenal insufficiency may have additional symptoms and signs related to hypothalamic or pituitary disease, such as loss of libido, menstrual disturbances, headache, visual disturbances, galactorrhea, features of acromegaly, or hypothyroidism. Compression of structures near the optic chiasm by the pituitary typically presents as visual-field deficits which are discussed below under pituitary disorders. Hyperpigmentation is rare, because circulating levels of ACTH and related peptides are low (1).

Adrenal crisis is much less common in patients with secondary adrenal insufficiency because the function of the renin–angiotensin–aldosterone system is generally preserved (2). Rarely, adrenal crisis can occur when there is sudden loss of pituitary function because of infarction or hemorrhage. Hypotension can result from sudden loss of ACTH secretion and concomitant decrease in cortisol levels. Although mineralocorticoids play a greater role in the maintenance of volume status, glucocorticoids have a role in maintaining peripheral vascular adrenergic tone as well (2).

The laboratory findings of primary adrenal insufficiency include hyponatremia, hyperkalemia, hypercalcemia, mild metabolic acidosis, hypoglycemia, anemia, lymphocytosis, and eosinophilia. Hypoglycemia is a common presentation in children and infants. Type I diabetics with adrenal insufficiency have a higher incidence of hypoglycemia than type I diabetics without cortisol deficiency. This occurs due to loss of the counter-regulatory effects of the adrenal gland, including loss of gluconeogenesis and lack of the

hyperglycemic effects of epinephrine (4). Hyponatremia is found in approximately 90% of patients and is due to sodium loss and volume depletion secondary to aldosterone deficiency. Mild hyponatremia may still be present in secondary adrenal insufficiency because of increases in vasopressin. Hyperkalemia associated with a mild hyperchloremic metabolic acidosis is also due to mineralocorticoid deficiency and occurs in about 60% of patients. In secondary adrenal insufficiency, the potassium level is usually normal because mineralocorticoid function is intact. One final potential laboratory abnormality is a rapid drop in hemoglobin, which may be seen with adrenal hemorrhage.

DIFFERENTIAL DIAGNOSIS

Because of the high mortality associated with acute adrenal insufficiency, the diagnosis should be considered and therapy instituted prior to confirmatory laboratory data. Hypovolemic shock that is refractory to standard resuscitation and unexplained changes in mental status should increase the clinician's suspicion for acute adrenal insufficiency. Abrupt discontinuation of steroids in the setting of chronic glucocorticoid use should prompt consideration for steroid administration in a patient who presents with other physiologic stressors.

The differential diagnosis of acute adrenal crisis includes other causes of cardiovascular collapse and shock including myocardial infarction, heart failure, hypovolemia, sepsis, and pulmonary embolism. Adrenal insufficiency should be in the differential diagnosis for any potential etiology of the acute abdomen and other gastrointestinal disorders. It should also be in the differential for fever of unknown etiology and altered mental status.

Chronic adrenal insufficiency is difficult to diagnose because the symptoms are more gradual in onset. It is often confused with a "flu-like" illness. The examination is often unremarkable. Laboratory evaluation may not be particularly revealing in all cases, especially with secondary insufficiency. The differential diagnosis includes psychiatric illness, chronic fatigue syndrome, and anorexia nervosa

(12). It should also be in the differential diagnosis for the evaluation of chronic "wasting syndromes," unexplained weight loss, and nonspecific arthralgias and myalgias.

ED EVALUATION

The first steps in the evaluation of adrenal insufficiency are a thorough history and a physical examination. The diagnosis may be overlooked because attention is often focused on the precipitating physiologic stressor or illness. Laboratory studies should include electrolytes, blood urea nitrogen (BUN), creatinine, glucose, complete blood count (CBC), baseline ACTH level, cortisol level, and thyroid function tests. Coagulation factors should be obtained with suspected adrenal or pituitary hemorrhage, especially in the setting of anticoagulant use or suspected disseminated intravascular coagulopathy. Chest x-ray, electrocardiogram, urinalysis, blood cultures, urine cultures, and any other test to rule out other potential stressors for an adrenal crisis should be obtained in the proper clinical setting.

The diagnosis of adrenal insufficiency cannot typically be made on the basis on a random single cortisol level. A low level, especially in the clinical setting of physiologic stressors, may suggest adrenal insufficiency. An early morning (8 AM) plasma cortisol level lower than 3 μg/dL confirms adrenal insufficiency, whereas a value higher than 15 μg/dL makes the diagnosis highly unlikely. Cortisol levels in the range of 3 to 15 μg/dL may be seen in patients with primary, secondary, or tertiary adrenal insufficiency.

Although it is not necessary in the ED, adrenocortical function can be evaluated with a Cortrosyn (Cosyntropin) stimulation test. Cortrosyn is a synthetic derivative of ACTH. This test only assesses the ability of the adrenal cortex to increase cortisol production in response to the ACTH derivative. It does not test the integrity of the HPA axis. The metyrapone test blocks cortisol synthesis which should increase ACTH production and can therefore be used to test hypothalamic and pituitary function. Differentiating between primary and secondary adrenal insufficiency may also be done by

measurement of basal plasma ACTH levels. An elevated ACTH level with a low cortisol level is consistent with primary adrenal insufficiency, and a low or normal ACTH level with a low cortisol level is consistent with secondary or tertiary adrenal insufficiency.

For the standard Cortrosyn stimulation test, 250 μg of IV or IM cortrosyn is administered and then cortisol levels are checked at 0, 30, and 60 minutes. Using absolute cortisol levels in critically ill patients to diagnose adrenal insufficiency is controversial as total cortisol levels may be affected by circulating proteins. Hypoproteinemia may lead to false-positive ACTH stimulation tests and overtreatment with steroids. Some authors have suggested using free cortisol or at least calculated free cortisol rather than total cortisol levels. Adrenal failure is likely if the peak post-cosyntropin cortisol level is <15 μg/dL. Cortisol levels >18 μg/dL are usually interpreted as excluding adrenal failure; however, cortisol levels <25 mg/dL may be inadequate in some critically ill patients. In sepsis, adrenal insufficiency is likely when baseline cortisol levels are <10 μg/dL or when the cortisol rises by <9 μg/dL after stimulation by 250-μg cosyntropin (2,8).

Abdominal computed tomography (CT) scan may demonstrate adrenal hemorrhage, metastasis, or calcification (seen with fungal adrenalitis and 50% of tuberculosis adrenalitis). These are incidental findings that are typically seen when these patients are being evaluated for potential causes of an “acute” abdomen. Head CT may demonstrate pituitary hemorrhage, infarction, or adenoma. Head CT is typically done in these patients when they present with altered mental status, severe headache (as with pituitary hemorrhage), or new visual disturbances (12).

KEY TESTING

- Electrolytes, BUN, creatinine, glucose
- CBC
- ACTH level
- Cortisol level
- Thyroid function tests

ED MANAGEMENT

Initial management of an adrenal crisis should include reversal of shock with vasopressors and isotonic saline as well as treatment of the precipitating illness. After fluid resuscitation, attention should be directed at treating hypoglycemia and other electrolyte abnormalities (Table 209.2). In severe cases, it may be necessary to treat hyperkalemia. The total body potassium level however is often low and total serum potassium value can decrease even more after glucocorticoids are administered. Symptomatic hyponatremia should also be corrected, generally with fluid restriction after the patient had been fluid resuscitated to a euvolemic state. There has been some success with the use of vasopressor receptor antagonists for the treatment of severe hyponatremia with primary adrenal insufficiency since ADH is increased due to salt wasting and excessive water losses from decreased aldosterone production. Hypertonic saline may rarely be indicated if the patient is symptomatic with altered mental status or persistent seizures from the hyponatremia. Monitoring of SvO_2 and central venous pressure through central venous access may be necessary, especially in the clinical setting of sepsis with hypotension.

TABLE 209.2
Treatment of Acute Adrenocortical Insufficiency (Adrenal Crisis)

1. Obtain adequate IV access. Central access to assist hemodynamic monitoring
2. Normal saline boluses to correct hypovolemia. Monitor carefully for signs of fluid overload
3. Obtain glucose level and replace accordingly
4. Send additional laboratory studies including electrolytes, creatinine, and baseline cortisol and ACTH levels
5. Hydrocortisone 100 mg IV (use dexamethasone 6–8 mg IV if ACTH stimulation test to be performed later for diagnostic purposes)
6. General supportive measures as indicated
7. Further evaluation to determine potential cause of crisis (electrocardiography, chest x-ray, blood and urine cultures)

Stress-dose steroids should be given prior to laboratory confirmation if adrenal insufficiency is suspected especially in the setting of vasopressor-resistant shock (8,13). Dexamethasone 10 mg IV is recommended for glucocorticoid replacement because it does not interfere with the cosyntropin test. Alternatively, an immediate intravenous bolus injection of hydrocortisone 100 mg should be followed by approximately 200 mg over 24 hours. Different dosing regimens have been suggested to mimic circadian rhythm variation in cortisol levels. Hydrocortisone 200 mg/d can be divided in doses every 8 hours or as a continuous infusion for 48 hours. Once the patient is stable, parenteral dosing can be changed to an oral dose of 50 mg every 8 hours for six doses, then taper to 30 to 50 mg/d in divided doses. When adrenal insufficiency presents concomitantly with hypothyroidism, steroids should be administered before giving levothyroxine so as not to precipitate adrenal crisis (14).

Glucocorticoid use has been studied extensively as a therapeutic agent in patients with sepsis. Although a short course of high-dose glucocorticoids (methylprednisolone 30 mg/kg) has been shown to be potentially harmful and ineffective in patients with sepsis, recent studies have demonstrated that a lower dose (hydrocortisone 200 to 300 mg/d) has been associated with decreased mortality and organ dysfunction in patients with vasopressor-resistant shock and relative adrenal insufficiency. Lower-dose steroids are, therefore, recommended in goal-directed therapy of sepsis patients presenting with hemodynamic instability (8,13).

Patients with known chronic adrenal insufficiency or chronic steroid use typically take a daily dose of 15 to 25 mg/d (15 mg in the morning and 10 mg at night) with slightly higher doses for primary than secondary adrenal insufficiency (20 to 25 mg vs. 15 to 20 mg). Adjustments should also be made based on patient's body surface area as well as other medications, which may affect cortisol metabolism. Patients with hyperthyoidism or using exogenous thyroxine may need to have the dosage of cortisol increased as well. Mineralocorticoids are usually only replaced in primary adrenal insufficiency with a fludrocortisone dose of 0.1 (0.05 to 0.25) mg/d taken as a single dose in the morning. Increased mineralocorticoids

may be needed in infants and neonates and may have to be adjusted in tropical climates (14). Hydrocortisone has some mineralocorticoid activity, whereas decadron and prednisolone have very little. When hydrocortisone is therefore administered at higher doses, additional mineralocorticoids may not be necessary. Dosing of steroids can be adjusted based on symptoms. Fatigue, nausea, myalgia, lack of energy, and weight loss may indicate underreplacement, whereas weight gain, central obesity, osteoporosis, impaired glucose tolerance, and hypertension may suggest overreplacement (14).

The most important component of crisis prevention is "*sick-day rules*" training for the patient and their families. They should be aware of stress-related glucocorticoid dose adjustments. Patients should have a hydrocortisone emergency kit which should contain 100 mg of solu-cortef to be given as an intramuscular injection (14). Intercurrent illness, such as respiratory infection associated with fever, requires doubling of the daily glucocorticoid dose until recovery. In the event of vomiting or diarrhea, the hydrocortisone dose should be doubled; if the medication is not kept down due to vomiting, glucocorticoids should be administered parenterally. For major stress events, such as surgery, trauma, or childbirth, 100- to 200-mg hydrocortisone should be administered over 24 hours (14).

DISPOSITION

Patients with acute adrenal insufficiency require admission to an intensive care unit. Subspecialty consultation should be requested. Patients in whom chronic adrenal insufficiency is suspected should be admitted to the hospital for evaluation. Rarely, patients with known chronic adrenal insufficiency who present with mild physiologic stressors may be discharged from the ED if the concomitant illness is addressed and the patient is started on stress-dose steroids with an appropriate taper. This approach requires appropriate consultation and very close follow-up.

Common Pitfalls

- Failure to consider the diagnosis of adrenal insufficiency in critically ill patients with septic shock or hypotension refractory to intravenous fluids and vasopressors.
- Failure to increase the steroid dose (to two to four times the usual regimen) in patients on chronic steroid therapy who have concurrent illness or physiologic stress.
- Failure to provide steroid replacement and adequate fluid resuscitation before performing an ACTH stimulation test.
- Failure to administer stress-dose steroids in a suspected case of myxedema coma before administering thyroxine as this could potentially precipitate an adrenal crisis.

CUSHING SYNDROME

Cushing syndrome is characterized by glucocorticoid excess secondary to increased adrenal cortisol production or chronic glucocorticoid therapy. The syndrome as originally described by Harvey Cushing in 1932 includes truncal obesity, hypertension, proximal muscle weakness, and striae. Pituitary oversecretion of ACTH, adrenal neoplasms, and ectopic ACTH production by a nonpituitary tumor are potential etiologies. The most common cause of Cushing syndrome is prolonged exogenous steroid administration.

Cushing disease, which is specifically due to excessive ACTH secretion from the pituitary, accounts for 70% of individuals with naturally occurring Cushing syndrome (15). Cushing disease typically occurs in women between 20 and 40 years of age and has a gradual onset. Most of these patients have pituitary microadenomas. When macroadenomas are responsible, patients may present with headaches or visual changes due to pressure on the optic chiasm.

Cushing syndrome can be caused not only by an ACTH-secreting carcinoma (e.g., small-cell bronchogenic carcinoma, pancreatic cancer, bronchial carcinoid, or carcinoma of the thymus) but rarely by nonpituitary tumors that secrete corticotropin-releasing hormone (16).

Adrenal neoplasms are another cause of Cushing syndrome, comprising about 20% of cases. In children, the most common

adrenal tumors just involve symptoms of access androgens. Among adults, Cushing syndrome alone is the most common followed by a mixed clinical presentation of both glucocorticoid and androgen excess. Adrenal tumors are usually unilateral, and approximately 50% are malignant (4).

CLINICAL PRESENTATION

Obesity and weight gain are common findings in Cushing syndrome (Table 209.3). Seventy-five percent of patients have deposition of fat in the face, described as “moon facies,” and around the neck and shoulders, known as a “buffalo hump.” Other fat accumulation occurs within the mesentery, producing truncal obesity. Half of patients have skin atrophy and abdominal striae which are characteristically reddish purple and wider than 1 cm. Other skin findings include easy bruising, poor wound healing, edema, acne or pigmentation, hirsutism, and a flushed appearance to the face. Old photographs are useful in showing the progression of changes, especially the development of moon facies, truncal obesity, and hirsutism. Patients also complain of fatigue and weakness. A proximal myopathy can be detected in about 60% of patients (15).

TABLE 209.3
Clinical Features of Cushing Syndrome

Feature	Percent
Truncal obesity	90–95
Thoracocervical/facial fat deposits (buffalo hump/moon faces)	80–85
Gonadal dysfunction	75–80
Menstrual irregularities	—
Loss of libido	—
Hirsutism	75–80
Hypertension	65–75
Psychiatric abnormalities	40–60
Ranging from depression to psychosis	—
Skin atrophy/striae formation	50–60
Proximal muscle weakness	50–60
Glucose intolerance/diabetes mellitus	50–60
Osteoporosis	40–50
Infection	—
Tuberculosis	—
Fungal	—
Ophthalmologic complications	20–30
Elevated intraocular pressures	—
Exophthalmos	—

Osteoporosis develops from mobilization of calcium, resulting in vertebral compression and pathologic fractures. Glucose intolerance and insulin resistance are other features, but overt diabetes is seen in only about 20% of patients. Hypertension is common. Menstrual abnormalities, sexual dysfunction, psychosis, emotional lability, and paranoia may also occur. Weight gain and growth retardation may be clinical signs in children (16).

Laboratory findings are generally nonspecific. The hemoglobin and hematocrit are high to normal, and the white blood cell count usually shows a leukocytosis with a predominance of neutrophils. The electrolytes are often normal, but there may be hypokalemia, hypochloremia, hyperglycemia, and hypercholesterolemia. Hypokalemic metabolic alkalosis may be present in cases of extreme cortisol excess (15).

Certain populations of patients with Cushing syndrome may have slightly different clinical presentations. Patients with ectopic ACTH syndrome caused by small cell lung carcinoma lack many of the

typical clinical features of Cushing syndrome such as obesity and weight gain. These patients may have a more dramatic presentation due to the rapid course of the malignancy as well as high ACTH levels and cortisol. Hyperpigmentation, myopathy, glucose intolerance, and hypokalemic alkalosis may predominate. Female patients with primary adrenal carcinomas may present with signs and symptoms of excess androgens which include hirsutism, acne, breast atrophy, deepening of the voice, temporal hair recession, and clitoral enlargement in addition to symptoms of glucocorticoid access (15). In contrast to nonmalignant causes of Cushing syndrome, adrenal carcinoma also has a more rapid onset and progression, with hypokalemia and abdominal pain as common symptoms.

Cushing syndrome during pregnancy deserves special mention, as it is associated with increased mortality owing to preeclampsia, hypertension, diabetes, wound breakdown, opportunistic infections, and fractures. Increased cortisol effects on the fetus include an increased rate of spontaneous abortion, perinatal death, premature birth, and intrauterine growth retardation. The diagnosis is difficult because of the physiologically increased cortisol levels during the second and third trimester of pregnancy (11).

DIFFERENTIAL DIAGNOSIS

Because many features of Cushing syndrome, such as obesity, hypertension, amenorrhea, and weakness, are common in other illnesses and thus nonspecific, the diagnosis can be difficult. Differentiation of Cushing syndrome from pseudo-Cushing syndrome can sometimes be a challenge. A pseudo-Cushing state is defined as having some of the clinical features and biochemical evidence of Cushing syndrome. Patients with chronic alcoholism may exhibit some characteristics suggestive of Cushing syndrome, but these abnormalities resolve after discontinuation of alcohol. Increased glucocorticoids may also lead to depression or emotional liability, which may make it difficult to differentiate between depression or other psychiatric illness and mild Cushing syndrome.

ED EVALUATION

It is difficult and most often not necessary to make a definitive diagnosis of Cushing syndrome in the ED. A single midnight serum cortisol level >7.5 mg/dL can be an early but not definitive finding. Several factors can affect random cortisol levels however. Diurnal variation makes random measurements of serum cortisol have little diagnostic value. Random serum cortisol levels during pregnancy and in females taking estrogens can also be falsely elevated as well.

Screening for Cushing syndrome can be done by a 24-hour urinary free cortisol determination, 1-mg dexamethasone suppression test, or midnight salivary cortisol. The 24-hour free cortisol can give cortisol levels lower than the true cortisol if the patient has a decreased GFR and higher levels with excess fluid intake. False-positive dexamethasone suppression test can occur with concomitant use of other medications such as dilantin, phenobarbital, and rifampin, as they can increase clearance of dexamethasone (15). Patients should be referred to an endocrinologist if the constellation of symptoms suggests the diagnosis.

KEY TESTING

- Electrolytes, BUN, creatinine, glucose
- CBC
- ACTH level
- Cortisol level—midnight cortisol level most helpful; random measurements are of little diagnostic value

ED MANAGEMENT

From the ED point of view the most important thing about managing Cushing syndrome is to first recognize the disease and then be aware of the potential increased mortality associated with it. Cushing syndrome is associated with increased risks of opportunistic infections as well as excess steroids masking a febrile illness or an acute abdomen. It is also important in the ED to be aware that these patients with a “Cushingoid” appearance from

exogenous steroid use may require excess steroids during an acute illness.

The treatment of Cushing syndrome for the endocrinologist focuses on reducing cortisol secretion, particularly surgical removal of a causative tumor. Complications of treatment that may be seen in the ED include postoperative diabetes insipidus (DI) and hypothyroidism, although hypothyroidism may take some time to present.

Patients who undergo bilateral adrenalectomy may develop Nelson syndrome, the effect of an enlarging pituitary tumor that secretes high levels of ACTH. This syndrome presents with hyperpigmentation and visual changes due to tumor encroachment on the optic chiasm. Up to 25% of patients who undergo bilateral adrenalectomy develop Nelson syndrome within 10 years of surgery.

When surgery is not successful or when it is not an option, as in metastatic adrenal carcinoma or ectopic ACTH production, hypercortisolism may be treated by medications that inhibit steroidogenesis. They include ketoconazole, metyrapone, mitotane, aminoglutethimide, and etomidate. Patients using these medications may require glucocorticoid replacement to avoid adrenal insufficiency. Rarely, when medication is not successful for hypercortisolism secondary to ectopic ACTH production, bilateral adrenalectomy may be necessary.

DISPOSITION

Well-appearing stable patients may be discharged with appropriate follow-up. Patients with impending adrenal crisis or any complications such as sepsis, or uncontrolled diabetes should be admitted to the hospital for monitoring and initiation of appropriate therapy.

Common Pitfalls

- Because the symptoms are common and nonspecific, the clinician may fail to consider the diagnosis of Cushing syndrome.

- Failure to recognize that patients with Cushing syndrome may have an immunocompromised state which can predispose them to developing opportunistic infections, reactivation of fungal infections and tuberculosis, as well as dissemination of otherwise self-limited viral disease such as herpes and chickenpox.
- Excess glucocorticoids may mask fever and other systemic signs of infection, including pain from an acute abdomen.
- Patients with Cushing syndrome from exogenous steroids may be at risk of adrenal crisis if they do not receive stress-dose steroids during an acute illness.

PHEOCHROMOCYTOMA

Pheochromocytomas are catecholamine-producing tumors that originate from chromaffin cells of the adrenal medulla. Tumors that arise from outside the adrenal gland are referred to as extra-adrenal pheochromocytomas or paragangliomas (17). They secrete norepinephrine, epinephrine, and occasionally other vasoactive peptides, but norepinephrine is usually predominant. The "rule of 10s" for pheochromocytomas is the following: 10% are extra-adrenal, 10% involve both adrenal glands, 10% are malignant, 10% are familial, 10% occur in children, and 10% are multiple (other than bilateral adrenal) (16).

Pheochromocytoma is present in $<1\%$ of hypertensive patients but is a potentially treatable cause of hypertension. If symptomatic pheochromocytomas are not treated, they may lead to acute myocardial infarction, congestive heart failure (CHF), stroke, or death. Pheochromocytoma may also however be completely asymptomatic. A retrospective study by the Mayo Clinic reported that 50% of diagnoses were identified at autopsy. Approximately 10% are discovered incidentally on CT (18). Pheochromocytomas may also occur in familial syndromes, including multiple endocrine neoplasia 2A and 2B, neurofibromatosis, and von Hippel–Lindau disease. Family history may be an important clue to the diagnosis, and family members of individuals with these syndromes should all be screened (10).

CLINICAL PRESENTATION

All patients with persistent uncontrollable hypertension should be screened for the diagnosis of pheochromocytoma. The clinical manifestations of pheochromocytoma are caused by the physiologic effects of the catecholamines and may be extremely variable (18). The classic triad of episodic headache, excessive sweating, and tachycardia occur together in less than 50% of these patients. Hypertension is the most common finding and may be sustained or paroxysmal, with varying frequency and duration. Sudden paroxysms of hypertension may cause the patient to feel a throbbing palpitation or headache. As an individual symptom, headache is the most common occurring in about 90% of symptomatic pheochromocytomas. Focal neurologic symptoms, blurred vision, and altered mental status may develop as well. Symptoms may be transient, lasting minutes or several hours. They may occur once a month or several times a week, but they usually increase in frequency as the tumor grows.

Attacks may occur in the absence of stimuli or with precipitating factors such as trauma, childbirth, exercise, abdominal pressure, or postural changes. These patients may have a hypertensive response to various medications and other agents including but not limited to the following: glucagon, steroids, droperidol, anesthesia induction, cocaine, amphetamines, tricyclic antidepressants, MAO inhibitors, certain cold medications, nasal decongestants, reglan, compazine, radiographic contrast, naloxone, and tyramine-containing foods (18,19). If a patient is being treated with beta-blockade alone in the ED for unexplained tachycardia, hypertension, or pulmonary edema and has a sudden spike in blood pressure, pheochromocytoma should be added to the differential diagnosis as well.

Other symptoms of catecholamine excess may be more subtle and persistent. These may include heat intolerance, increased sweating, weight loss, nausea, weakness, anxiety, dyspnea, orthostatic hypotension, and signs of hyperglycemia such as polyuria and polydipsia. In pregnancy, the symptoms may be positional as well. The gravid uterus may compress the tumor in a supine position

leading to normal blood pressure with sitting or standing and hypertension when lying flat (11).

Chronic constriction of the arterial and venous beds may decrease the total intravascular volume, resulting in orthostatic symptoms despite a baseline increase in blood pressure. Acute arterial vasospasm from elevated catecholamine levels may rarely lead to limb ischemia (17).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of pheochromocytoma is broad and includes most conditions in which there is a hyperadrenergic state and any disease processes associated with a hypertension.

Pheochromocytoma should be included in the differential diagnoses of any acute cardiovascular or cerebral vascular process presenting with refractory hypertension or orthostatic hypotension. Other hyperdynamic states commonly seen in the ED include hyperventilation, panic attacks, premenopausal hot flashes, hypoglycemic reaction, acute alcohol or opiate withdrawal, drug reaction, illicit drugs, hyperthyroidism, labile essential hypertension, carcinoid syndrome, serotonin syndrome, altered mental status, pulmonary embolus, and toxemia of pregnancy (18). Abrupt withdrawal of clonidine or beta-blockers as well as patients on MAO inhibitors who ingest tyramine-containing food may have a similar presentation as well. The absence of proteinuria may differentiate pheochromocytoma from hypertension associated with preeclampsia. Pheochromocytoma in pregnancy is associated with a markedly increased fetal and maternal morbidity and mortality if an antenatal diagnosis is not made (11).

ED EVALUATION

The ED evaluation typically does not involve immediate testing for pheochromocytoma. With a high clinical suspicion, as in patients with a family history of an MEN 2, von Hippel–Lindau, or imaging that is highly suggestive of a pheochromocytoma, fractionated plasma metanephrines may be ordered during the initial ED

evaluation. Outpatient 24-hour urine collection for catecholamines and their metabolites can be ordered if the patient is considered to have a low risk for pheochromocytoma such as with an asymptomatic adrenal mass or paroxysmal self-limiting hyperadrenergic symptoms. Overall, the 24 hour urine collection for fractionated metanephrines and catecholamines has a high sensitivity and specificity (98% sensitivity and specificity). An elevated fractionated plasma metanephrine level has a highest sensitivity (96% to 100%) but a lower specificity (85% to 89%) (20). The sensitivity is lower in patients over 60 years and also in patients with dopamine-secreting neoplasms. Most laboratories now measure fractionated metanephrines and catecholamimes rather than total plasma levels due to decreased false-positive and negative tests with the newer methods. Patients may still have inaccurate results if they are concomitantly taking certain antipsychotic medications, antihypertensive medications, or were recently administered contrast agents. The method of obtaining plasma and urine samples may also still lead to false-positive or negative testing even with the more sensitive tests (20).

Both magnetic resonance imaging and CT scan have about a 98% to 100% sensitivity. The specificity is only about 70% however due to the high prevalence of incidental adrenal tumors. MRI is more accurate than CT scan at differentiating pheochromocytoma from other adrenal tumors. CT with IV contrast has been demonstrated to precipitate a hypertensive crisis, so it is suggested to use a lower-osmolarity contrast agent if there is a high clinical suspicion for pheochromocytoma. A low-osmolarity contrast agent may increase diastolic blood pressure but does not increase plasma catecholamine levels and is not associated with hypertensive crises (21). Scintigraphy using a norepinephrine analog can also be used to identify extra-adrenal pheochromocytomas (16). These tests are not necessary for initial management in the ED.

KEY TESTING

- MRI or CT scan image of adrenal gland

ED MANAGEMENT

The priority for the emergency physician is to treat the hypertensive emergency, if present, and volume expansion. Sodium nitroprusside (starting at 1 to 3 μg/kg/min) helps to control hypertension through its arterial and venous dilating effects. If pheochromocytoma is suspected or hypertension is resistant to treatment with nitroprusside, alpha-blockade can be achieved with intravenous phentolamine (2.5- to 5-mg bolus IV at 1 mg/min followed by a continuous infusion titrated to effect). Because of phentolamine's short half-life, doses may be repeated every 3 to 5 minutes. Parenteral beta-blockade is used to treat dysrhythmias and resistant hypertension but should be given only after alpha-blockade so as to avoid paradoxical hypertension from unopposed alpha effects (16). Labetalol has been used as an alternative, but its use is controversial because it has much greater beta- than alpha-blockade. The use of labetalol has been associated with some case reports of paradoxical hypertension (18). Newer antihypertensive drugs such as Carvedilol (Coreg) have similar side effects to labetalol and should be avoided in the preoperative treatment of a pheochromocytoma. Nicardipine may also be used with a starting dose of 5 mg/hr and titrated up to 15 mg/hr with increases of 2.5 mg/hr every 15 minutes.

Any patient who is already diagnosed with a pheochromocytoma should undergo surgical resection after appropriate medical management. There has been a lack of consensus regarding the recommended preoperative drug regimen. Oral alpha-agonists, calcium channel blockers, and angiotensin inhibitors have all been recommended. For tachyarrhythmias, oral beta-blockers or calcium channel blockers are recommended after appropriate alpha-agonist blockade. Typically, patients will be placed on an oral alpha-agonist such as prazosin, doxazosin, terazosin, or phenoxybenzamine 2 to 3 days before starting beta-blockers. In most cases, this medication regimen is started 7 to 14 days prior to surgery to normalize blood pressure and to avoid a catecholamine-induced crisis during surgery. Various oral calcium channel blockers may be used as well including amlodipine, nicardipine, nifedipine, and verapamil.

Calcium channel blockers can supplement alpha-blockers in patients who do not have adequate blood pressure control as well as replace alpha-blockers in patients that are having adverse side effects such as orthostatic hypotension (19).

It has also been suggested that the patient should be put on a high-salt diet preoperatively as well (if no contraindication such as CHF) to help expand the contracted blood volume. In addition, there is an extensive list of medications which is mentioned above that should be avoided as they may precipitate release of catecholamines (19).

DISPOSITION

Typically, patients with uncontrolled hypertension and symptoms suggesting hypertensive crisis require admission. Stable patients who are asymptomatic should be referred for prompt follow-up with an endocrinologist for further evaluation and testing.

Surgical resection is the definitive treatment of choice once a pheochromocytoma has been identified and located. The recurrence rate after surgical resection is $<10\%$, and the 5-year survival after surgery is approximately 95%. About 25% of patients continue to have hypertension after removal of the pheochromocytoma; the cause is believed to be irreversible vascular damage from previous uncontrolled catecholamine excess, or underlying essential hypertension, but the blood pressure in these patients is usually readily controlled with standard antihypertensive regimens.

Common Pitfalls

- Be aware of certain medications (listed earlier in the text) and higher-osmolarity contrast media, as potential precipitants of hypertensive crisis in patients with pheochromocytoma.
- Pheochromocytoma should be considered in patients who complain of transient symptoms that have resolved by the time of ED evaluation. These patients may benefit from appropriate referral and outpatient evaluation.

- Because patients with pheochromocytoma are often hypovolemic, sudden blood loss or sudden loss of vascular tone can result in precipitous and severe hypotension.

PITUITARY DISORDERS

The pituitary gland is divided into an anterior and posterior lobe. The anterior pituitary hormones are regulated by hypothalamic releasing and inhibitory hormones and by negative feedback of the target glands' hormone production. Prolactin, which affects lactation, is the only pituitary hormone not directly increased by hypothalamic regulation but may be inhibited by PIF (prolactin-release inhibitory factor). Antidiuretic hormone (also referred to as ADH or vasopressin) and oxytocin are produced in the hypothalamus and travel through the pituitary stalk to the posterior pituitary gland where they are stored and released. ADH regulates blood pressure, stimulates water reabsorption, and reduces excretion of urine. Oxytocin helps to regulate uterine contraction and lactation as well (22).

In addition to prolactin, ADH, and oxytocin, the pituitary gland secretes TSH (thyroid-stimulating hormone), FSH and LH (follicle stimulating hormone and luteinizing hormone), ACTH (adrenocorticotropic hormone), and GH (growth hormone) in response to corresponding hypothalamic releasing hormones. In turn, these stimulating hormones affect the secretions of the thyroid, gonads, and adrenal glands.

Tumors of the pituitary may present with hypofunction, hypersecretion, or mass effect. Pituitary hemorrhage, infiltration, destruction, injury, or necrosis more often presents with hypofunction. Hyperfunctioning pituitary adenomas may be the cause of Cushing disease or secondary hyperthyroidism, as discussed above, as well as prolactinomas and acromegaly (22).

Prolactinomas typically present as lactation in males and females but may be associated with other symptoms such as hypogonadism, headaches, or visual-field deficits secondary to mass effect. If there are no signs of mass effect or headaches, the ED evaluation would

typically only involve a pregnancy test (for females), a review of the patient's medication list, and an endocrinology referral if no other obvious cause of lactation is identified. Multiple medications have been associated with increased lactation and discontinuation of them may prevent the need for a more exhaustive laboratory workup and imaging. The presence of severe headache and/or signs of mass effect with lactation however may warrant a CT or MRI to rule out more serious pathology such as an inflammatory process, malignancy, or aneurysm.

The evaluation for acromegaly, which is typically due to a growth hormone–secreting pituitary macroadenoma, can be referred to an endocrinologist for further confirmatory testing unless there is other secondary pathology requiring ED evaluation such as CHF or hyperglycemia. In order to properly recognize and refer a patient with potential acromegaly, the following typical characteristics of this disease process are listed: coarse facial features, thick coarse skin, enlargement of limbs, fingers, and ears, macroglossia and malocclusion of teeth with gaps, hypertension, CHF, arrhythmias, diabetes mellitus, carpal tunnel syndrome, neuropathic joints, signs of pituitary mass effect, and pituitary insufficiency (22).

Evaluation of pituitary disease in the ED most often focuses on hypopituitarism as this clinical spectrum of disease more often requires immediate interventions. Hypopituitarism is a decreased production of one or more of the regulatory hormones which leads to decreased end-organ function.

CLINICAL PRESENTATION

The clinical manifestations of hypopituitarism include end-organ hypofunction such as hypothyroidism, hypogonadism, and adrenal insufficiency. Pituitary adenomas are the most common cause of acquired hypopituitarism. Hypogonadism is the most frequent manifestation of the endocrine abnormalities.

Pituitary adenomas can cause headache and vision loss when larger tumors compress the optic chiasm or optic nerve. The most common visual defect is bitemporal hemianopsia which is a loss of

vision in the outer half of both right and left visual fields. If the tumor extends lateral to the sella where the pituitary sits, cavernous sinus involvement can lead to impingement of cranial nerves III, IV, V1, V2, and VI. Patients with a sellar mass pressing on the optic chiasm should have a Humphrey visual-field testing by an ophthalmologist. Pituitary adenoma is found in about 10% to 20% of autopsies, but the incidence of clinical symptoms attributed to pituitary tumors is quite low at about 2 to 8 per 100,000 persons per year (23).

Pituitary insufficiency may also be caused by other intrasellar and parasellar tumors, ischemic necrosis secondary to sickle cell anemia, vasculitis, or diabetes, granulomatous disease (sarcoidosis, tuberculosis, Wegener granulomatosis), cavernous sinus thrombosis, infections (fungal, meningitis, syphilis), empty sella syndrome, aneurysmal dilation of the internal carotid, autoimmune destruction, surgical removal, radiation-induced destruction of pituitary tissue, traumatic brain injury, subarachnoid hemorrhage, or postpartum pituitary necrosis (Sheehan syndrome). Secondary hypopituitarism may be due to abnormalities of the hypothalamus or pituitary stalk and compression by an aneurysm or tumor (16).

Hypopituitarism occurring in the postpartum patient after an episode of hypotension or shock is known as *Sheehan syndrome.* These patients may fail to lactate in the postpartum period and may develop amenorrhea, gonadal atrophy, and symptoms of hypothyroidism and adrenal insufficiency. Some, however, remain undiagnosed until a later exposure to stress triggers an adrenal crisis.

When hypopituitarism occurs from an acute loss of pituitary function, it is referred to as *pituitary apoplexy*. Infarction or hemorrhage of an enlarged pituitary gland or pituitary tumor is the most common cause. The presenting signs are sudden onset of severe headache, visual changes, meningismus, decreased level of consciousness, and cranial nerve palsies. Headache is the most common symptom and it often mimics the presentation of a subarachnoid hemorrhage (22).

Destruction of at least 90% of the pituitary is required before complete panhypopituitarism becomes clinically apparent, and chronic or partial hypopituitarism may present with subtle signs of single or incomplete hormone deficiencies. When a patient with known hypopituitarism presents to the ED because of a concurrent illness unrelated to the endocrine system or the central nervous system, he or she should continue to receive usual hormonal replacement therapy, including stress doses of corticosteroids, if necessary.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of hypopituitarism is so broad because of the wide spectrum of endocrine functions that the HPA regulates. Growth hormone deficiency may initially present as lack of energy or decreased exercise tolerance. Gonadal dysfunction may present with amenorrhea in a menstruating woman or with impotence in a man. Hypothyroidism may often be initially misdiagnosed as depression or chronic fatigue. ACTH deficiency typically presents in later stages and may present with a spectrum from fatigue and vague gastrointestinal symptoms, with or without hypoglycemia, to adrenal crisis from an intercurrent stressor (16). Posterior pituitary involvement may present with polydipsia and polyuria secondary to decreased antidiuretic hormone from DI. Patients with DI may also have seizures, headaches, and visual-field defects in addition to evidence of volume contraction.

ED EVALUATION AND MANAGEMENT

The diagnosis of hypopituitarism is generally made after extensive testing by an endocrinologist, including measurement of specific hormone levels and magnetic resonance imaging of the pituitary. The treatment of hypopituitarism consists of lifelong hormone replacement.

Emergency hormone replacement is rarely needed in the ED. Suspected deficiencies in growth hormone as well as gonadotropin hormones can be referred to an endocrinologist. Blood samples

should be sent for measurement of plasma cortisol, prolactin, ACTH, and TSH levels, and thyroid function studies before instituting cortisol replacement if the patient is stable and pituitary disease is suspected. As mentioned above, decadron can be given initially to the unstable patient with suspected adrenal insufficiency rather than hydrocortisone, so as not to interfere with the ACTH stimulation test. Glucocorticoid replacement should precede administration of levothyroxine if myxedema coma is also suspected, because thyroxine accelerates the metabolism of cortisol and can precipitate an adrenal crisis (22).

Electrolyte panels should also be obtained looking for hypernatremia if central DI is suspected when the patient has symptoms of excess thirst or urination. It is also important to rule out other causes of polyuria and polydypsia such as new-onset diabetes mellitus. With central DI, the patient will have a very dilute urine with a low specific gravity despite the presence of increased serum osmolality and elevated sodium (16). Typically, patients with central DI can drink enough fluids to replace urinary loss. If hypernatremia is severe, patients may require fluid replacement with dextrose containing hypotonic IV fluids. Do not correct the sodium more than 0.5 mmol/L/hr. In central DI, the drug of choice is desmopressin which is a synthetic analog of ADH. It can be given IV, subcutaneous, intranasal, or orally two to three times a day. Carbamazepine, chlorpropamide, thiazide diuretics, and nonsteroid anti-inflammatory agents may control polyuria in mild cases by enhancing the effect of antidiuretic hormone on the renal tubules and collecting duct (16).

KEY TESTING

- Electrolytes, BUN, creatinine, glucose
- Cortisol
- Prolactin
- ACTH
- TSH/TFT

DISPOSITION

Patients with evidence of shock or hemodynamic instability should be admitted to an intensive care unit setting and have prompt endocrine evaluation if hypopituitarism is suspected. Other patients should be referred to an endocrinologist for further testing and diagnosis.

Common Pitfalls

- Most hypopituitarism is chronic and difficult to diagnose. Some patients may have been given psychiatric diagnoses.
- Acute loss of pituitary function is also difficult to diagnose unless a pituitary abnormality is apparent on an imaging study.

CRITICAL INTERVENTIONS

- In suspected but unconfirmed acute adrenal insufficiency, administer dexamethasone rather than hydrocortisone, as it will not interfere with the ACTH (cosyntropin) stimulation test; do not wait for cosyntropin test to give patient steroids
- If pheochromocytoma is suspected or hypertension is resistant to treatment with nitroprusside, administer IV phentolamine (2.5- to 5-mg boluses)
- Beta-blockade is used to treat tachyarrhythmias and resistant hypertension but should be used only after alpha-blockade has been accomplished, to avoid paradoxical hypertension from unopposed alpha-effects
- Patients with Cushing syndrome may require exogenous steroids during stress to avoid an adrenal crisis

CHAPTER 210 Disorders of Sodium and Water Metabolism

Sandra A. Craig

Serum sodium concentration and serum osmolality are normally maintained within a narrow range by homeostatic mechanisms involving thirst, antidiuretic hormone (ADH), and renal handling of sodium.

Sodium and chloride ions are normally separated from the glomerular filtrate in the ascending limb of the loop of Henle, leaving behind a hypotonic filtrate, and resulting, in the absence of ADH, in the net excretion of free water. Increases in serum osmolality above the normal range of 280 to 300 mOsm/L are detected by osmoreceptor neurons in the hypothalamus and cause an increase in thirst and in circulating levels of ADH. ADH acts on the collecting ducts of the renal tubules, increasing free-water reabsorption. This reabsorption results in the excretion of low volumes of urine of relatively high osmolality and a return of the serum osmolality toward normal. ADH is also secreted in response to decreases in intravascular volume and in response to noxious stimuli such as pain, fear, nausea, hypoxia, and surgical procedures (1).

Sodium balance is regulated independently of ADH by atrial natriuretic peptide–mediated changes in the degree of sodium reabsorption in the renal tubule. Hypovolemic states such as those caused by hemorrhage or dehydration are associated with increased sodium absorption in the renal tubule and decreased delivery of sodium to the tubular diluting sites. Conversely, increases in intravascular volume and glomerular filtration rate suppress

proximal tubular sodium reabsorption, resulting in increased delivery of sodium to diluting sites.

Disorders of water balance can be traced to abnormalities of thirst or water acquisition, glomerular filtration rate, renal sodium transport, or ADH metabolism.

HYPONATREMIA

CLINICAL PRESENTATION

Hyponatremia is physiologically significant insofar as it reflects a state of extracellular hypo-osmolality in which free water shifts from the vascular space to the intracellular space (see Fig. 210.1). Although the resulting cellular edema is well tolerated by most tissues, the brain is sensitive to changes in cell volume. The clinical manifestations of hyponatremia, usually associated with serum sodium levels <130 mEq/L, are related primarily to cerebral edema. Symptoms include headache, difficulty in concentrating, confusion, lethargy, agitation, nausea, vomiting, and seizures. Anorexia and muscle cramps are also common.

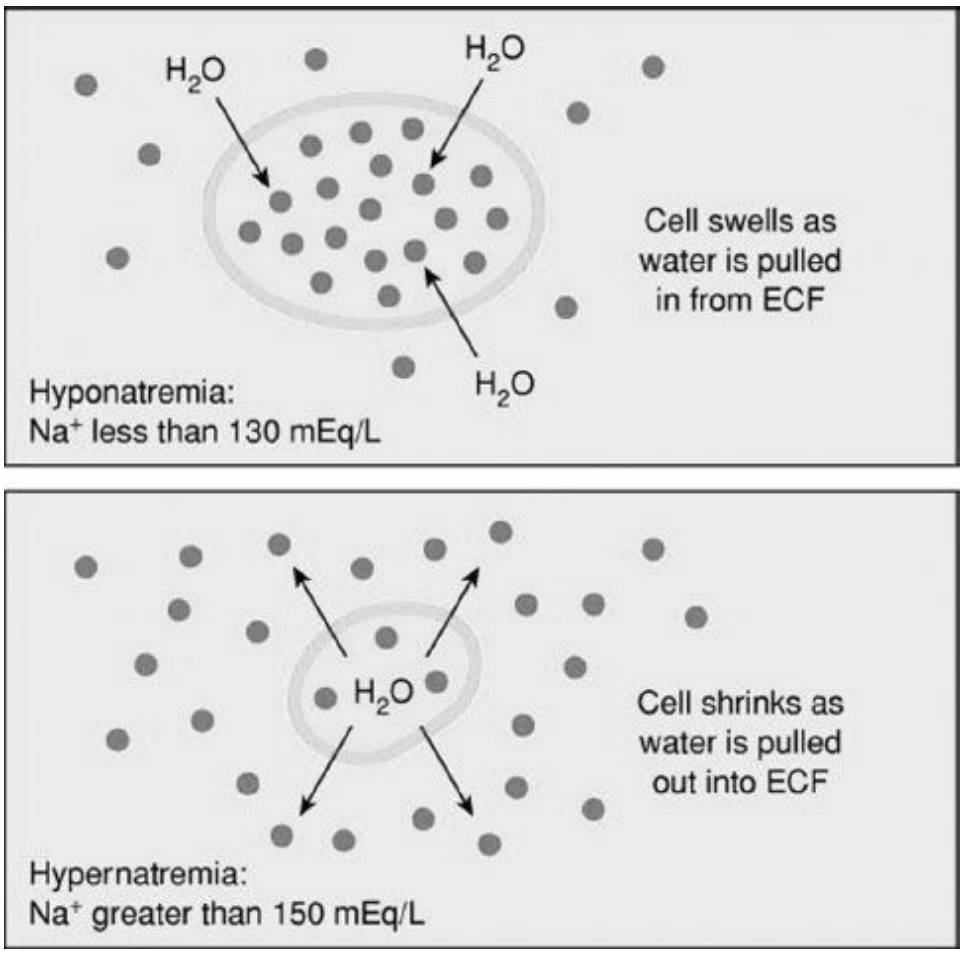

FIGURE 210.1 Effect of extracellular sodium on cell size.

The incidence and severity of manifestations increase not only with the degree of hyponatremia but also with the rate at which it develops. When the serum sodium level falls gradually over a period of days or weeks, the brain can compensate via active extrusion of solutes and passive movement of water into the extracellular space. Serum sodium values as low as 110 mEq/L may thus be reached with minimal symptomatology. However, a rapid fall in the serum sodium, for example, from a normal level to $<$125 mEq/L within 48 hours, exceeds the capacity of these compensatory mechanisms and can lead to profound cerebral edema, causing coma or brainstem herniation (1).

DIFFERENTIAL DIAGNOSIS

The diagnosis of hyponatremia rests entirely on the ability to obtain and measure accurately the concentration of sodium in the patient's serum. The possibility of erroneous sampling should always be considered, especially when the reported value does not seem consistent with the clinical situation. Was the specimen properly labeled? Was it drawn from a venous site proximal to an infusion of hypotonic saline or dextrose 5% in water (D_5W)? Is there an error in laboratory measurement or recording? When an error of some kind is suspected, a fresh sample should be obtained and tested before diagnostic or therapeutic procedures are initiated.

There are several clinical conditions in which an accurately measured, low serum sodium concentration does not represent a true hypo-osmolar state. The most common is moderate to severe hyperglycemia. Extracellular glucose accumulation causes movement of free water into the extracellular space, resulting in hyponatremia and a normal or increased serum osmolarity. The serum sodium value decreases by approximately 2.4 mEq/L for each 100-mg/dL increase in the serum glucose value (2). This hyponatremia is not physiologically significant, and it resolves as normoglycemia is reestablished. This phenomenon, termed hypertonic hyponatremia, is also noted in patients treated with mannitol, glycerol, sorbitol, radiocontrast media, or IVIG suspended in 10% maltose solution (1).

Pseudohyponatremia refers to a falsely low serum sodium measurement in patients whose plasma contains excessive amounts of lipid or protein. In this situation, the plasma water in which sodium is dissolved occupies a smaller proportion of the blood specimen. Laboratory methods that measure sodium content per unit of plasma report low sodium levels, even though the concentration of sodium in serum water is normal. This situation occurs when the serum sodium concentration is measured by the flame emission spectrophotometry or indirect potentiometry method but not with direct potentiometry. Indirect potentiometry is performed in approximately 66% of chemistry laboratories in the United States (3). The emergency physician must remain aware of this phenomenon. Because serum osmolarity is normal, water metabolism is completely undisturbed. Hyperlipidemia severe enough to produce

pseudohyponatremia is almost always associated with a lipemic appearance of the serum. Hyperproteinemia of a sufficient degree to cause pseudohyponatremia is commonly caused by multiple myeloma or administration of intravenous immune globulin. Point-of-care testing utilizes direct potentiometry, and serum sodium results remain accurate in the setting of hyperlipidemia or hyperproteinemia.

Measurement of serum osmolality will distinguish true hypotonic hyponatremia from these other states.

ED EVALUATION

The ED evaluation of true hyponatremia has two goals. The first is to define the chronicity of the hyponatremic state, which must be based primarily on historic clues. Patients with a paucity of symptoms despite sodium levels <125 mEq/L are likely to have chronic hyponatremia. Acute hyponatremia is less common than chronic hyponatremia and should be suspected in patients with a history of sudden free-water loading (e.g., patients with schizophrenia who may exhibit psychogenic polydipsia, infants given only tap water for 1 to 2 days, and postoperative patients who have received hypotonic IV fluids, enemas, or bladder irrigation fluids) (1).

The second goal in the evaluation of the hyponatremic patient is to establish the cause. Hyponatremia should be classified as hypovolemic, euvolemic, or hypervolemic based on the history and physical examination (Fig. 210.2). Classification helps to narrow the list of causes and aids in the selection of therapy. Hypovolemic patients demonstrate signs of volume depletion, such as tachycardia, orthostasis, dry mucous membranes, diminished skin turgor, oliguria, or azotemia. A low fractional excretion of sodium (<0.5%) and low fractional excretion of urea (<55%) may be helpful in identifying subtle cases of hypovolemia (4). Hypervolemia is manifested by the presence of congestive heart failure, peripheral edema, or ascites. Patients who appear neither volume depleted nor volume overloaded are classified as having euvolemic hyponatremia.

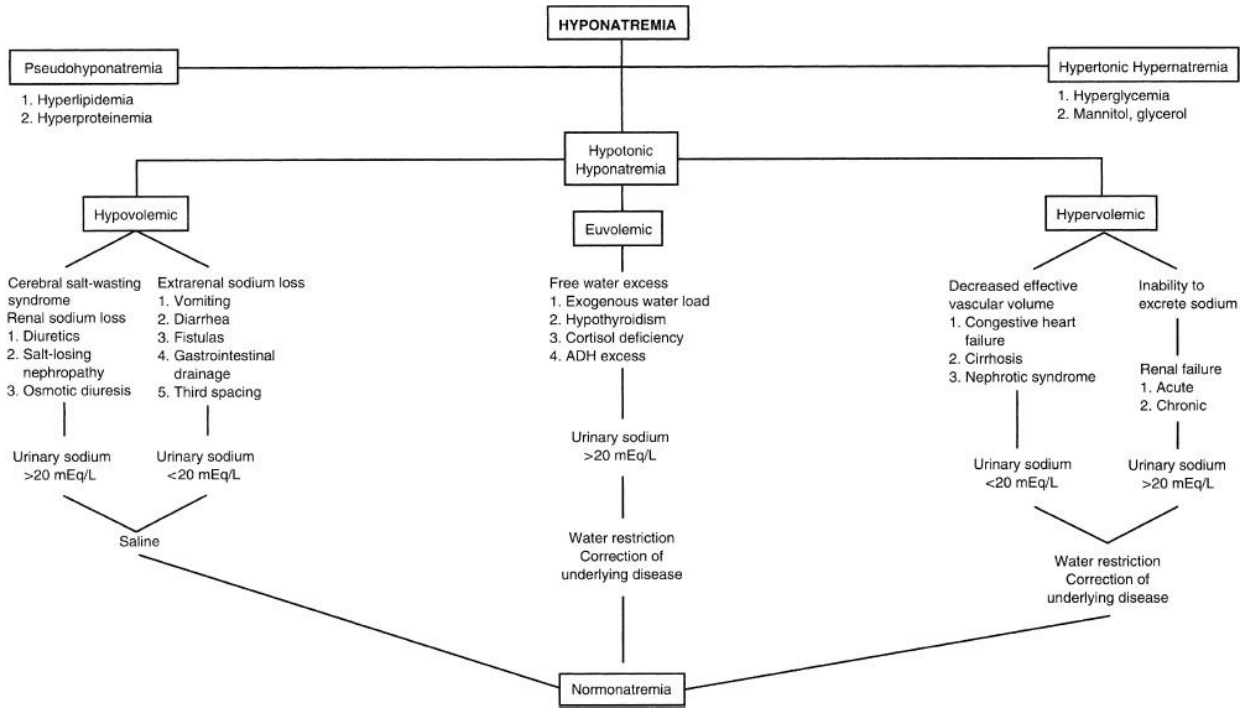

FIGURE 210.2 Algorithm for diagnosis and treatment of hyponatremia.

Hypovolemic Hyponatremia

Patients with hypovolemic hyponatremia have decreased total body sodium stores. Nonrenal causes of sodium depletion include vomiting, diarrhea, fistulas, gastrointestinal drainage tubes, excessive sweating, and third spacing of fluids from peritonitis, pancreatitis, or burns. Cerebral salt-wasting syndrome should be considered in patients with intracranial disease such as traumatic brain injury, tumor, stroke, meningitis, or intracranial surgery (1). Renal causes of sodium loss include osmotic diuresis and salt-wasting nephropathies such as medullary cystic disease and obstructive uropathy. Thiazide diuretics (hydrochlorothiazide, metolazone, indapamide) are one of the most common causes of severe hyponatremia, especially in the elderly population. Hyponatremia typically occurs between 5 and 25 days after initiating therapy. The precise mechanism remains unknown.

The nonrenal causes of hypovolemic hyponatremia are associated with a urine sodium value of <20 mEq/L, and renal causes are

associated with a urine sodium value of >20 mEq/L. As a general principle, hyponatremia does not develop unless free-water intake exceeds free-water excretion. In these hypovolemic conditions, hyponatremia is maintained by low glomerular filtration rates that preclude adequate free-water excretion and by high levels of ADH secreted in response to hypovolemia.

Hypervolemic Hyponatremia

Hyponatremic patients with clinical signs of total body sodium excess, usually evidenced by the presence of edema, are classified as having hypervolemic hyponatremia. Two situations are associated with inappropriate increases in body sodium stores. The first is renal retention of sodium in response to states of decreased effective intravascular volume (e.g., congestive heart failure, cirrhosis, and nephrotic syndrome). The second is an inability of the kidney to excrete ingested sodium loads because of acute or chronic renal insufficiency.

In patients with hypervolemic hyponatremia, the evaluation should include a search for signs of decreased cardiac output, increased portal vein pressure, nephrotic range proteinuria, or renal insufficiency. Patients with decreased effective vascular volume caused by heart failure, cirrhosis, and nephrotic syndrome typically have urine sodium values that are <20 mEq/L; those with renal insufficiency typically have values >20 mEq/L.

Euvolemic Hyponatremia

Patients who appear neither dehydrated nor edematous are considered to have euvolemic hyponatremia. As with the other types of hyponatremia, the low serum sodium concentration implies that free-water intake has occurred at a rate that exceeds the kidneys' ability to excrete it. This disorder can occur in patients with psychogenic polydipsia (who, if renal function is normal, must drink at least 15 L of water per day), but it has also been noted in patients who have been given tap water enemas or in infants given tap water bottle feedings. This group is identified by the history of excessive

free-water administration and by a urine osmolality that is appropriately low, generally <100 mOsm/L (5). Hyponatremia in association with a grossly normal volume status may also be seen in some patients with renal failure who have ingested more free water than can be promptly excreted, given their decreased glomerular filtration rate.

An often considered but uncommon cause of euvolemic hyponatremia is the syndrome of inappropriate ADH secretion (SIADH) (Table 210.1), in which ADH is secreted in excessive amounts despite the presence of hyponatremia and adequate intravascular volume. This syndrome is associated with a variety of pulmonary and central nervous system (CNS) conditions, malignancy, acquired immunodeficiency syndrome (AIDS), and the use of a number of medications (Table 210.2) (1). The diagnostic criteria for SIADH are as follows:

- Hypotonic hyponatremia
- Inappropriately concentrated urine (UOsm >100 mOsm/L)
- Normal renal excretory function
- Normal adrenal and thyroid function
- Absence of hypovolemia and dehydration
- Absence of edema

Measurement of ADH levels is not helpful in making the diagnosis, because the ADH level is also commonly elevated when hyponatremia is linked to other causes.

Two additional causes of euvolemic hyponatremia must be excluded before making the diagnosis of SIADH or exogenous water toxicity—hypothyroidism and cortisol deficiency. Hyponatremia caused by cortisol deficiency is rarely associated with a serum sodium level <120 mEq/L, and it corrects promptly after glucocorticoid replacement. Hypothyroidism has been associated with sodium levels as low as 110 mEq/L and is treated by thyroid hormone replacement. The mechanism of hyponatremia in these conditions remains incompletely understood.

Postoperative hyponatremia is a form of euvolemic hyponatremia that deserves special mention because of its iatrogenic nature and potential for serious sequelae. Surgical patients experience multiple

stimuli for ADH secretion such as pain, fear, and nausea. Numerous case reports describe development of acute severe hyponatremia and elevated levels of ADH in otherwise healthy patients who receive hypotonic IV or bladder irrigation fluids after elective surgery. Permanent neurologic sequelae, including brainstem herniation and death, are known to occur. For this reason, hospitalized patients should never be exposed to hypotonic fluid infusions in the immediate postoperative period (1).

KEY TESTING

- Obtain serum sodium level from correct patient, correct site
- Serum osmolality is low in cases of true hypotonic hyponatremia
- Obtain serum glucose and calculate corrected serum sodium if hyperglycemic
- Check serum protein and lipids if lack of symptoms suggests pseudohyponatremia

ED MANAGEMENT

The treatment of hyponatremia depends on the severity of symptoms and the rate at which hyponatremia has developed. It is important to distinguish between acute and chronic hyponatremia, because the pathophysiology and appropriate treatment are different.

Patients with acute hyponatremia (i.e., developing in <48 hours) are at risk for severe CNS effects, such as obtundation, seizures, and brainstem herniation, at levels of 125 mEq/L or less. Cerebral edema develops as free water shifts from the vascular space to the intracellular space within a period too short to allow the neurons to compensate by extruding cellular solutes. Cardiopulmonary arrest may occur secondary to brainstem herniation (1,6). Meticulous attention must be given to maintaining adequate airway and oxygenation. The source of excess free water must be immediately identified and eliminated. Patients with obtundation or seizures should receive hypertonic (3%) saline to increase the serum sodium rapidly but only enough to arrest the progression of symptoms. An increase of 4 to 6 mEq/L is usually sufficient to reverse cerebral

edema and terminate hyponatremic seizures. Further correction should proceed at an overall rate of 8 to 10 mEq/L in the first 24 hours, and serum sodium levels should be closely monitored. In theory, acute hyponatremia can be corrected more rapidly without risk of adverse consequences, but, in practice, it may be difficult to be certain of the time course over which hyponatremia developed and the degree of cellular compensation that may already have occurred.

Chronic hyponatremia must be managed especially carefully. Overaggressive therapy is potentially more dangerous than the condition itself. In these patients, the brain cells have had time to reduce their solute content to match that of the hypo-osmotic serum and are relatively protected from cerebral edema. When patients such as these have the serum sodium concentration increased rapidly, a significant number develop an osmotic demyelination syndrome, characterized by focal myelin destruction in the pons and extrapontine areas (6,7). Symptoms begin 1 to 7 days after overly rapid correction of the serum sodium and consist of dysarthria, dysphagia, seizures, altered mental status, quadriparesis, and hypotension (6,7). The diagnosis is confirmed by magnetic resonance imaging (MRI) of the brain, although lesions may not be seen until 10 to 14 days after the onset of symptoms. The condition is typically associated with permanent sequelae. The risk of osmotic demyelination syndrome appears to be low in patients whose chronic hyponatremia is corrected at a rate of <0.5 mEq/L/hr. In order to stay well clear of correction rates that risk osmotic demyelination, the goal should be to increase serum sodium by 8 to 10 mEq/L in the first 24 hours, 14 to 16 mEq/L in the first 48 hours, and 16 to 18 mEq/L in the first 72 hours (6). Osmotic demyelination syndrome is rarely associated with rapid correction of hyponatremia of <24 hours duration (5,7).

Hypertonic saline is indicated only for the initial correction of severely symptomatic acute or chronic hyponatremia. The appropriate volume of hypertonic saline required to produce a given change in the serum sodium level may be estimated using the following formula:

$$\text{Required volume} = \frac{(Na_{desired} - Na_{current})\ (TBW)}{Na_{IV\ fluid} - Na_{current}}$$

For a 50-kg woman with 60% total body water (TBW) and serum sodium of 113 mEq/L, the volume of 3% NaCl (513 mEq/L) required to raise the serum sodium by 4 mEq/L would be

$$\frac{(4\ \text{mEq/L})\ (50\ \text{kg} \times 0.6)}{(513 - 113)} = 0.3\ \text{L or } 300\ \text{mL}$$

One might give 100-mL boluses of 3% NaCl every 10 minutes, repeated up to a total of 300 mL until resolution of seizures and then proceed with other steps to increase the serum sodium by a total of 8 to 10 mEq/L for the first 24 hours. Hypovolemic hyponatremia should be treated with normal saline. Hypervolemic hyponatremia is often difficult to treat, because the underlying disorders are usually not readily reversible. Sodium and water restriction is usually the best alternative. Diuretics may result in transient loss of sodium and water but may ultimately decrease the glomerular filtration rate and limit free-water excretion. Patients with euvolemic hyponatremia should have their free-water intake restricted, and any identifiable underlying cause should be treated. Diuretic-induced hyponatremia responds to withdrawal of the offending medication, liberalized sodium intake, and repletion of total body potassium.

The parenteral ADH (arginine vasopressin) receptor blocker conivaptan (Vaprisol) was developed and Food and Drug Administration (FDA) approved it in 2008 for the treatment of euvolemic hyponatremia such as SIADH and hypervolemic hyponatremias resulting from congestive heart failure, cirrhosis, or the nephrotic syndrome. Several double-blind placebo-controlled trials demonstrated that conivaptan is more effective than water restriction alone in increasing serum sodium in hospitalized patients with serum sodium of 115 to 130 mEq/L. More recently, a V2 selective receptor antagonist, tolvaptan, has been FDA-approved for oral use in patients with euvolemic and hypervolemic hyponatremia. At this time, the FDA has limited its use to 30 days in patients without known liver dysfunction, due to early reports of severe liver

injury. Further research is needed to define the appropriate clinical indications and safety profile of these agents (6,8–10).

CRITICAL INTERVENTIONS

- Distinguish acute from chronic hyponatremia based on history and mental status.
- Intervene immediately in cases of severe hyponatremia with obtundation or seizures.
- Correct chronic hyponatremia at < 0.5 mEq/L/hr in order to avoid osmotic demyelination syndrome.
- Monitor serum sodium closely during therapy to avoid overly rapid correction.

DISPOSITION

Evidence-based guidelines for disposition of patients with hyponatremia do not exist, so admission decisions must be made case by case based on thorough understanding of underlying physiology. Decisions should be based on the chronicity of hyponatremia and the severity of symptoms more than on the absolute serum sodium level. Essentially all patients with acute hyponatremia should be admitted. These patients usually present with severe neurologic signs: obtundation, seizures, or cardiopulmonary arrest caused by brainstem herniation. Patients with chronic hyponatremia and significant symptoms such as lethargy, vomiting, seizures, or obtundation should also be admitted, so that serial sodium levels can document improvement of serum sodium at the appropriate rate. Patients with asymptomatic or minimally symptomatic chronic hyponatremia (nausea without vomiting or altered mental status) in whom a clear cause of hyponatremia is identified (e.g., thiazide use) can be discharged with instructions to discontinue the offending agent and have serum sodium levels rechecked in 24 to 48 hours.

Common Pitfalls

- Consider the possibility of sampling error, hyperglycemia, hyperlipidemia, or hyperproteinemia before making the diagnosis

of hypotonic hyponatremia.
- Consider the possibility of hyponatremia in high-risk groups, including elderly patients on diuretics, psychiatric patients, infants given only tap water, postoperative patients receiving hypotonic fluid therapy, and patients with malignancy or AIDS.
- Acute symptomatic hyponatremia should be recognized and treated quickly to avoid cerebral edema and brainstem herniation. Chronic hyponatremia should be corrected at an overall rate less than 0.5 mEq/L/hr to minimize the risk of osmotic demyelination syndrome.
- Accidental overcorrection of serum sodium is common. Follow serum sodium levels closely during therapy.

HYPERNATREMIA

Hypernatremia is considerably less common than hyponatremia, because even a small increase in the serum sodium concentration is a potent stimulus to thirst. Elevated serum sodium levels develop only in patients who are unable to experience thirst or are unable to gain access to water. Hypernatremia is most often seen at the extremes of age.

CLINICAL PRESENTATION

Hypernatremia reflects a state of intravascular hyperosmolarity that results in the efflux of water from the intracellular space to the extracellular space. Signs and symptoms are primarily related to CNS dehydration. Mental status changes range from irritability to lethargy, confusion, delirium, seizures, and coma. Muscle tone tends to be increased, as are deep tendon reflexes. CNS hemorrhage into the subarachnoid, intracerebral, or subdural space is seen in severe cases and is thought to be caused by tearing of bridging veins as they are stretched by shrinkage of brain tissue (11).

As with hyponatremia, the severity of symptoms correlates with the severity of hypernatremia and the rate at which it develops. When the serum sodium value increases gradually over several days or weeks, neurons respond by retaining excess quantities of

osmotically active solutes. This retention minimizes the efflux of free water from the cells and delays the onset of symptoms until relatively extreme levels of hypernatremia are achieved. When hypernatremia develops rapidly (in <48 hours), this adaptive mechanism is overwhelmed, and symptoms develop at a lower serum sodium level.

ED EVALUATION

It is helpful to classify hypernatremia as hypovolemic, hypervolemic, or euvolemic on the basis of clinical signs of dehydration or volume overload. Classification helps to narrow the list of causes and aids in the selection of therapy (Fig. 210.3).

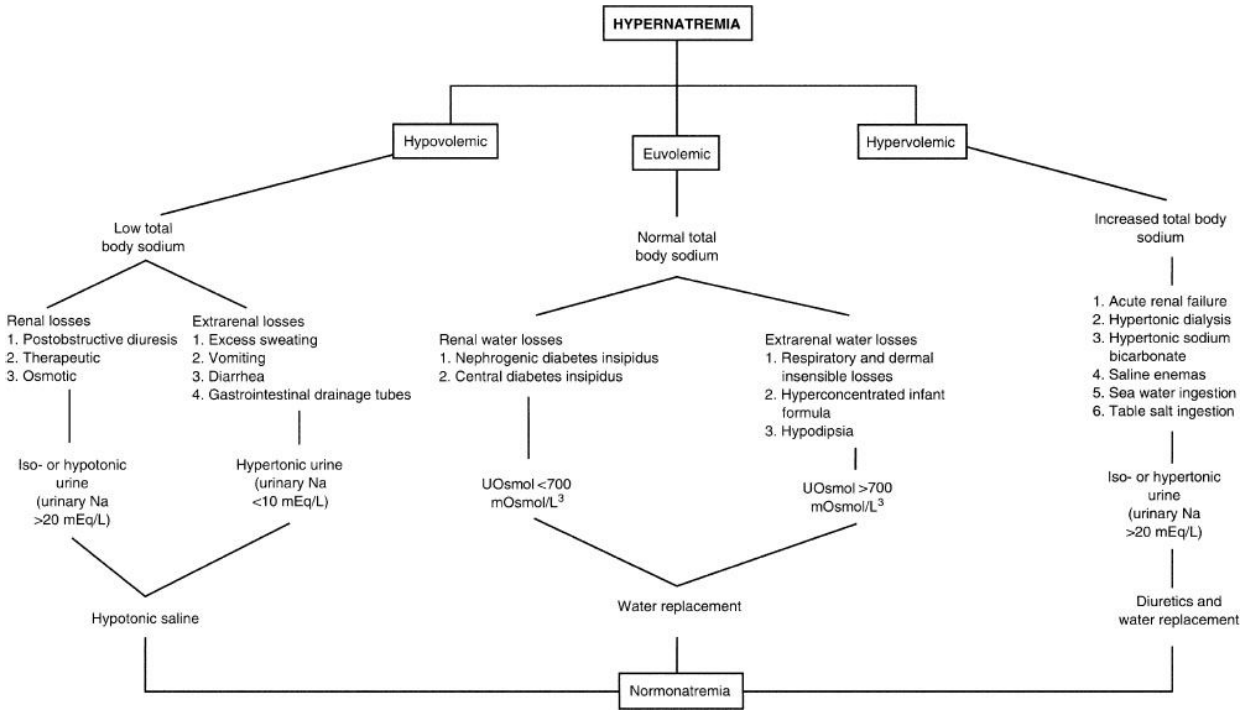

FIGURE 210.3 Algorithm for diagnosis and treatment of hypernatremia.

Hypovolemic Hypernatremia

Patients with hypovolemic hypernatremia exhibit signs of dehydration such as tachycardia, orthostasis, dry mucous membranes, diminished skin turgor, oliguria, and azotemia.

Hypovolemia implies that total body sodium stores are decreased, and hypernatremia implies that free water has been lost to a greater degree than sodium. There are nonrenal and renal causes. Nonrenal causes of hypovolemia include excessive sweating, protracted vomiting, diarrhea (hyperosmotic nasogastric feedings, acute gastroenteritis, lactulose), and gastrointestinal drainage tubes; the urine sodium concentration is <10 mEq/L. Renal causes include postobstructive, osmotic, or therapeutic diuresis or cerebral salt-wasting syndrome; the urine sodium is >20 mEq/L. To achieve a hypernatremic state, the loss of hypotonic fluids must be coupled with inadequate free-water replacement (1).

Hypervolemic Hypernatremia

Patients with signs of fluid overload (e.g., pulmonary edema or peripheral edema) are classified as having hypervolemic hypernatremia. This group has increased total-body sodium stores with a smaller increase in total-body free water. The differential diagnosis includes acute renal failure, use of hypernatremic dialysate solutions, seawater or soy sauce ingestion, and excessive administration of sodium in the form of hypertonic saline, sodium bicarbonate, hyperalimentation, or saline enemas or emetics. An enteral overdose of as little as 4 teaspoons of table salt can result in a serum sodium concentration of 160 mEq/dL in the average adult. Patients who have taken an overdose of table salt but have had no intake of water may not have overt signs of hypervolemia. The urine sodium value is >20 mEq/L in these cases.

Euvolemic Hypernatremia

Patients who appear neither dehydrated nor edematous are considered to have euvolemic hypernatremia, implying normal total body sodium stores and an isolated loss of free water. This condition may occur in comatose or intubated patients whose insensible free-water losses are not adequately replaced. It is common in patients whose insensible losses are accelerated because of tachypnea or fever. Euvolemic hypernatremia is seen in infants whose powdered

formula is inadequately diluted or, rarely, in persons with an intrinsic defect in the hypothalamic thirst drive, a condition known as essential hypernatremia. In all of these cases, the urine osmolarity is appropriately >700 mOsm/L during water deprivation.

Diabetes insipidus causes euvolemic hypernatremia due to inappropriate loss of free water in the urine. In this condition, there is an inability to maximally concentrate urine during periods of water deprivation. This may be due to inadequate hypothalamic secretion of ADH (central diabetes insipidus) or an inability of the kidneys to respond adequately to circulating ADH (nephrogenic diabetes insipidus). In either case, hypernatremia is accompanied by inappropriately dilute urine (UOsm <700 mOsm/L[3]), even during water restriction.

KEY TESTING

- Obtain serum sodium in patients with altered mental status, especially at extremes of age
- Urine sodium distinguishes renal from nonrenal causes of hypovolemic hypernatremia
- Euvolemic hypernatremia with urine osmolarity <700 suggests diabetes insipidus
- Consider brain CT in those with severe hypernatremia to identify CNS hemorrhage

ED MANAGEMENT

The underlying cause of hypernatremia should be identified and eliminated. When choosing the concentration and volume of fluid used to correct serum sodium, as with the treatment of hyponatremia, it is important to distinguish between acute hypernatremia (<48 hours duration) and chronic hypernatremia (>48 hours duration), because cell physiology and the response to therapy are different.

Acute hypernatremia is less common and usually develops in the setting of inadvertent sodium administration. Severe neuronal dehydration develops, and the cells are unable to rapidly adapt by

retention of additional cellular osmoles. Subarachnoid, intracerebral, and subdural hemorrhage may occur. Acute hypernatremia should be corrected rapidly, using D_5W or oral administration, until acute manifestations begin to improve. Diuretics should be added for patients with clinical signs of volume overload.

More commonly, hypernatremia develops over several days or weeks because of slower loss of hypotonic fluid or insensible free-water loss. Neurons adapt by retaining cellular solutes, minimizing movement of free water out of the cell. Rapid administration of hypotonic saline or D_5W in these patients carries a risk of cerebral edema. Chronic hypernatremia should be normalized at a steady rate of <0.5 mEq/L/hr (12).

Hypotensive patients should receive 0.9% normal saline (154 mEq/L) until they are normotensive and can be started on hypotonic fluids. The free-water deficit can then be estimated using the following formula:

$$\text{Water deficit} = \frac{\text{TBW}\ (\text{Na}_{\text{actual}} - \text{Na}_{\text{desired}})}{\text{Na}_{\text{actual}}}$$

where total body water (TBW) is 60% of the usual body weight. Replacement fluids can be administered as D_5W or oral water, with 30% of fluids given over the first 24 hours, and 70% of fluids given over the next 48 hours (1).

Patients with diabetes insipidus should receive DDAVP in addition to free-water replacement. Hypervolemic patients with chronic hypernatremia may require diuretic therapy in addition to free-water replacement.

CRITICAL INTERVENTIONS

- Distinguish acute from chronic hypernatremia based on history and mental status.
- Intervene immediately in cases of acute hypernatremia to avoid CNS hemorrhage.
- Correct chronic hypernatremia at less than 0.5 mEq/L/hr so as to avoid cerebral edema.

DISPOSITION

Evidence-based guidelines for disposition of patients with hypernatremia do not exist. Admission decisions must be made case by case based on a thorough understanding of underlying physiology. Decisions should be based on the chronicity of hypernatremia and the severity of symptoms more than on the absolute serum sodium level. Factors such as underlying illness, age, and ability to sense thirst and acquire water should be considered. Essentially all patients with acute hypernatremia should be admitted. These patients often experience severe neurologic signs: irritability, lethargy, confusion, delirium, seizures, and coma. Computed tomography (CT) of the brain is indicated in severely symptomatic patients to look for subarachnoid, intracerebral, or subdural hemorrhage, which would mandate neurosurgical consultation.

Patients with chronic hypernatremia and significant symptoms, such as irritability, lethargy, confusion, seizures, or coma, should be admitted so neurologic status can be monitored. Patients should be admitted until serial sodium levels document improvement of serum sodium steadily over 48 to 72 hours. Patients with asymptomatic chronic hypernatremia in whom a reversible cause of hypernatremia is addressed (i.e., fever, dehydration, access to water) can be discharged and have serum sodium levels checked in 24 to 48 hours.

Common Pitfalls

- Consider the possibility of hypernatremia in high-risk patients: infants and demented, comatose, or intubated patients without access to free-water replacement.
- Chronic hypernatremia should be corrected gradually in order to minimize the risk of cerebral edema.

CHAPTER 211 Disorders of Potassium Metabolism

Daniel J. Combs and Robert G. Buckley

OVERVIEW OF POTASSIUM HOMEOSTASIS

Potassium is the body's major intracellular cation. The average 70-kg person has approximately 3,500 mEq of potassium—98% of which resides intracellularly—primarily within muscle cells (1). The remaining 2% is located extracellularly, where the potassium plasma concentration is maintained within a narrow range of 3.5 to 5 mEq/L (2). Because of this enormous intracellular-to-extracellular gradient, potassium serves as the main determinant of resting cell membrane potential, wherein small shifts can result in important alterations in nerve and muscle depolarization (1). Therefore, both hypo- and hyperkalemic states can lead to life-threatening impairments in neuromuscular and cardiac function.

The average adult takes in roughly 100 mEq of dietary potassium daily, with 90% renally excreted. The remaining 10% is excreted in stool, and that amount can increase dramatically in diarrhea, where concentrations as high as 90 mEq/L can be reached (2). Similarly, sweat contains only a negligible amount of potassium (roughly 5 mEq/L) but may lead to clinically significant losses in warm climates.

The sodium-potassium-ATPase pump (Na/K-ATPase) is a key controller of intracellular and extracellular potassium. By pumping 2 potassium ions into the cell and 3 sodium out, it exerts a crucial effect in maintaining a negative resting membrane potential (1). The Na/K-ATPase pump is activated by a number of factors such as

increases in extracellular potassium, insulin, catecholamines, and aldosterone (3) (Fig. 211.1). Na/K-ATPase pump activation by catecholamines or insulin in skeletal muscle results in huge, rapid intracellular shifts. Acidosis leads to increased plasma potassium as hydrogen ions shift into cells and potassium shifts out. Similarly, hypertonicity (e.g., diabetic ketoacidosis [DKA] or mannitol infusion) leads to a shift of water and potassium out of the cell.

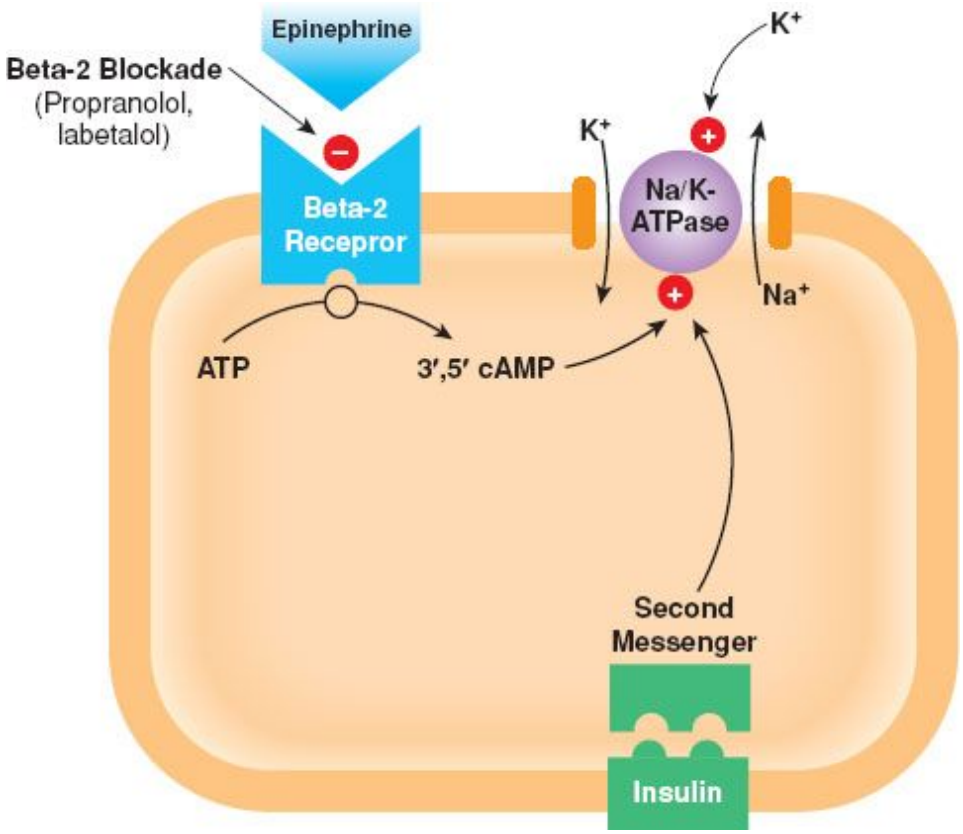

FIGURE 211.1 Schematic depiction of various endogenous and exogenous modulators of intracellular potassium. (Graphics courtesy of Judy A. Christensen, Medical Graphics Division, Naval Medical Center San Diego.)

HYPERKALEMIA

CLINICAL PRESENTATION

Hyperkalemia is defined as a serum potassium concentration >5 mEq/L. Pseudohyperkalemia due to red blood cell hemolysis during

venipuncture is probably the most common emergency department (ED) presentation (4,5), whereas true, life-threatening hyperkalemia most commonly presents in patients with renal failure (6). Clinical signs or symptoms are rarely apparent with mild-to-moderate hyperkalemia and are nonspecific (e.g., generalized weakness, muscle cramps, or vague gastrointestinal symptoms) (7,8). The most critical presentation involves impairment of cardiac conduction including asystole or ventricular fibrillation (8). Hyperkalemia generally becomes apparent only when a characteristic electrocardiographic (ECG) pattern (9) or cardiac rhythm is encountered, or a blood chemistry panel detects the elevated level. It is, therefore, imperative to maintain a low threshold for obtaining serum electrolytes in all patients presenting with nonspecific muscular weakness or any ECG abnormalities compatible with the diagnosis of hyperkalemia.

DIFFERENTIAL DIAGNOSIS

Apart from pseudohyperkalemia, the various causes of true hyperkalemia are due to one of the three disorders: Increased potassium intake, transcellular shifts, or impaired renal excretion (Table 211.1). All of these disorders should be considered when attempting to explain an elevated serum potassium level.

TABLE 211.1
Common Causes of Hyperkalemia in Emergency Department Patients

Disorder	Etiology
Pseudohyperkalemia	Hemolysis (in vitro or venipuncture)
	Extreme leukocytosis or thrombocytosis (e.g., leukemia)
Increased potassium intake	Increased oral intake
	Potassium-containing medications (e.g., penicillins)
	Massive transfusion
Transcellular shift of potassium	Insulin deficiency (e.g., DKA)
	Beta-2 blockade (e.g., propranolol)
	Acidosis
	Cell breakdown (e.g., DIC, crush, burns, tumor lysis syndrome)
	Hyperkalemic periodic paralysis
	Drugs (e.g., digoxin toxicity, succinylcholine)
Impaired renal excretion	Oligoanuric renal failure
	Severe volume depletion
	Hypoaldosteronism (e.g., addisonian crisis)
	Type 4 RTA
	Drugs
	Potassium-sparing diuretics
	ACE inhibitors
	Trimethoprim
	Pentamidine
	NSAIDs

DKA, diabetic ketoacidosis; DIC, disseminated intravascular coagulopathy; NSAIDs, nonsteroidal anti-inflammatory drugs.

ED EVALUATION

A serum potassium level should be obtained on all patients who present with even minimal symptoms and any of the disorders listed in Table 211.1. This is particularly true in the dialysis-dependent patient. Once an elevated potassium level is suspected, an ECG should be obtained immediately. If pseudohyperkalemia is suspected and the ECG is normal, blood should be redrawn (if possible without a tourniquet) and the patient kept on a cardiac monitor until a normal level is confirmed.

ECG changes (Fig. 211.2) are classically described as evolving in a stepwise fashion: Starting with symmetrical T-wave peaking, followed by P-wave flattening, QRS widening, and, if untreated, a

sinusoidal ECG pattern (9). In one early investigation, ECG abnormalities were found in 64% of 39 patients with potassium levels of 5.5 mEq/L or more and in all patients with levels >6.7 mEq/L (10). Though ECG changes generally do not occur with potassium levels below 6.5 mEq/L, there is no absolute correlation between the severity of cardiac conduction abnormalities and potassium elevation (11). For example, Acker et al. (12), in a study of 127 hyperkalemic episodes, found that only 46% of all patients with serum potassium levels <6.8 mEq/L had typical ECG abnormalities, whereas nearly half of those with higher levels lacked any characteristic ECG changes. Therefore, though the ECG is too insensitive to rule out hyperkalemia, all hyperkalemic patients who have typical changes on ECG should be aggressively managed (13).

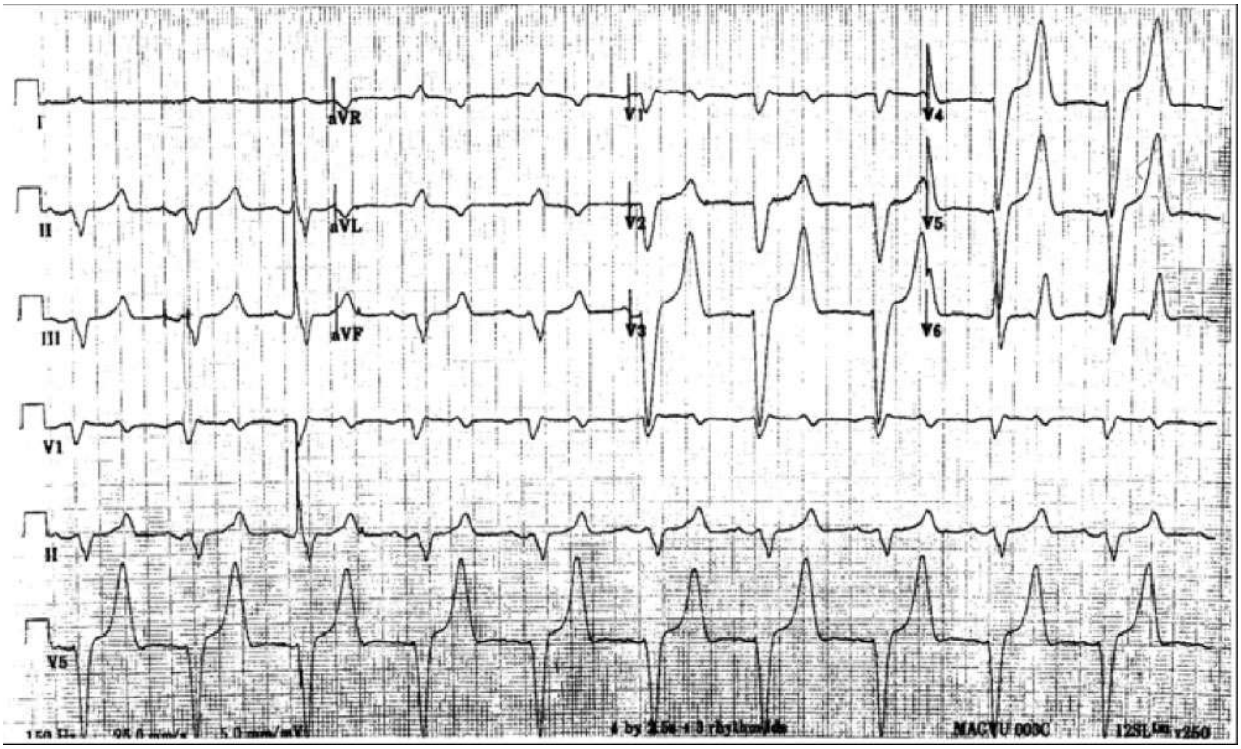

FIGURE 211.2 ECG in patient with potassium level of 7.3 mEq/L. Hyperkalemia-related findings in this ECG include peaked T-waves, prolonged PR intervals, decreased amplitude of P-waves, and widening of QRS complex.

The initial ED workup of hyperkalemia should also include a complete blood count, chemistry panel, serum ketones, if DKA is suspected, and a digoxin level if applicable. Arterial blood gas analysis may also help explain the cause of hyperkalemia when an obvious diagnosis is not apparent.

ED MANAGEMENT

All patients with hyperkalemia should be placed on a cardiac monitor. The need for therapy and urgency with which therapy is given is based primarily on the severity of ECG alterations, the degree and chronicity of the potassium elevation, the severity of neuromuscular dysfunction, the presence of underlying cardiac disease, and, finally, when apparent, the underlying cause of the hyperkalemia. The emergency treatment of hyperkalemia follows four strategies: (a) directly antagonize the membrane destabilizing effects of hyperkalemia (e.g., calcium salts); (b) translocate extracellular potassium into cells (e.g., insulin, glucose, albuterol, and sodium bicarbonate [$NaHCO_3$]); (c) remove potassium from the body (e.g., cation exchange resins and dialysis); and (d) treat the underlying cause of hyperkalemia (e.g., Fab fragment antidotal therapy for digoxin toxicity, hydrocortisone for addisonian crisis, or discontinuation of drugs associated with hyperkalemia, such as potassium-sparing diuretics, angiotensin-converting enzyme inhibitors, or trimethoprim-sulfamethoxazole).

Calcium salts should be given immediately to all patients with QRS widening on ECG or dysrhythmias. The typical regimen is calcium gluconate 10%, one to two 10-mL ampules (2 mL/kg in children) infused over 2 minutes each, and repeated in 5 minutes if no effect is noted on ECG (2,14). Calcium chloride 10%, which contains roughly three times the amount of elemental calcium per 10-mL ampule, may be infused in roughly equimolar amounts to calcium gluconate (13). Calcium gluconate, however, is safer when infused through a peripheral vein because it causes less venous irritation, and calcium chloride causes severe tissue necrosis if tissue infiltration should inadvertently occur.

There is a time-honored caution that calcium should be avoided in patients taking digoxin. Digoxin's chief effect on cardiac myocytes is to antagonize the Na/K-ATPase pump. The subsequent rise in intracellular sodium results in an increase in intracellular calcium through a number of mechanisms, one of which is a sodium-calcium exchange pump. This rise in intracellular calcium, in turn, prolongs calcium's binding to contractile proteins. Exogenous calcium administration may theoretically lead to a potentiation of this effect, but recent studies have questioned the validity of this concern (15,16). Pending further study, it remains prudent to use calcium with caution in patients with hyperkalemia specifically due to acute digoxin toxicity. In this setting, Fab fragment is considered a first-line therapy (17).

Insulin stimulates Na/K-ATPase activity via an intracellular second messenger and has an onset of action of 20 to 30 minutes, lowering serum potassium levels by roughly 0.5 to 1 mEq/L in 1 to 2 hours (2). Among the immediate treatments for hyperkalemia, insulin is considered the most efficacious and reliable (8). The typical dose is regular insulin 0.1 U/kg up to a 10-U bolus. In euglycemic patients, 25 to 50 g of dextrose should be given. Glucose should be avoided in hyperglycemic patients ($>$200 mg/dL), as extracellular hypertonicity leads to a shift of free water and moves potassium out of the cell. For the same reason, some authors advocate giving insulin and glucose more slowly (e.g., 500 mL of D_{10} W with 10 U of regular insulin infused over 60 minutes). This slow infusion is probably prudent in stable patients with mild ECG changes, with bolus therapy reserved for more severely symptomatic patients with advanced ECG alterations. In all instances, close monitoring (i.e., hourly) of fingerstick and serum glucose should be done to avoid hypoglycemia (13).

$NaHCO_3$ leads to a shift of potassium into cells as hydrogen ions shift extracellularly. Alkalemia leads to increased potassium in the distal convoluted tubules (DCTs) as hydrogen ions are conserved (5). Its effects are most beneficial in the acidotic patient and should generally be avoided in the dialysis-dependent patient with hyperkalemia (13). The standard bolus is one 50-mEq ampule

infused over 5 minutes, (2 to 3 mL/kg in children) (14). The onset of action occurs in 5 to 10 minutes and lasts for roughly 2 hours. $NaHCO_3$ can lead to acute fluid overload in patients with congestive heart failure (CHF) or renal failure and may lead to tetany and seizures in hypocalcemic patients when alkalosis induces increased calcium-protein binding and decreased ionized calcium. Current literature has called into question the efficacy of $NaHCO_3$ as treatment for hyperkalemia although it remains an accepted treatment and has a role as adjunctive therapy for some patients (8,18).

Nebulized albuterol (10 to 20 mg) can be used as an immediate therapy to shift potassium intracellularly via beta-2 receptor stimulation (13,19). There appears to be a dose-related response and the treatment may be repeated after 120 minutes. Combining albuterol with insulin-glucose therapy seems to reduce potassium levels more effectively than either treatment alone (18). The onset and duration of action of albuterol are similar to those of $NaHCO_3$. Though only modest increases in heart rate and blood pressure occur, albuterol should be used with caution in patients with known cardiac disease. It is generally not needed in mild cases.

As the most common presentation of hyperkalemia in most EDs is in the patient with chronic kidney disease who has missed a scheduled dialysis session, a renal consultant should be contacted when hyperkalemia is detected. Hemodialysis is highly effective in reducing extracellular potassium, with standard coils removing roughly 40 mEq over the first hour. Comparatively, peritoneal dialysis can remove only 5 mEq of potassium per liter of dialysate per hour.

Sodium polystyrene sulfonate (SPS) is a cation exchange resin that can remove up to 1 mEq of potassium for each gram used. Its onset of action is 4 to 6 hours (20); therefore, it has generally been reserved for stable patients with less severe ECG abnormalities who are not undergoing emergent hemodialysis. The standard oral regimen is 30 g mixed with 50 mL of 20% sorbitol solution to induce diarrhea. Alternatively, a 1-hour retention enema using 50 g of SPS

and 200 mL of 20% sorbitol can be given just prior to the patient's hospital admission.

However, recent reviews have called into question not only the efficacy of SPS, but also its safety when given with sorbitol (20). The FDA has issued a warning against the use of sorbitol with SPS in light of reports of colonic necrosis and other gastrointestinal adverse events (21). Given the weak evidence of benefit and the potential for complications, SPS is currently being used much less commonly for hyperkalemia. Certainly, its use concomitantly with sorbitol would certainly be contraindicated in patients with suspected bowel obstruction, ileus, or recent abdominal surgery.

Hyperkalemia in the euvolemic or hypovolemic patient with normal renal function should be treated with volume expansion to optimize the glomerular filtration rate. All hyperkalemic ED patients who require emergent treatment should have continuous intravenous access and cardiac monitoring. They should have glucose and electrolytes measured after the first hour of treatment, then at least every 2 hours thereafter.

The specific cause of hyperkalemia should be considered in all patients, with particular attention paid to medications. Digoxin and other medications mentioned earlier, as well as others—the most obvious being oral potassium supplements—should be considered.

CRITICAL INTERVENTIONS

- Obtain an ECG in all suspected cases.
- If characteristic hyperkalemic abnormalities are found (peaked T-waves, P-wave flattening, QRS widening), initiate treatment immediately with
  - calcium gluconate 10%, 10 mL over 2 minutes if ECG reveals widened QRS or dysrhythmias (may repeat in 5 minutes);
  - regular insulin 0.1 U/kg up to 10 U IVP. Add 25 g of D_{50} W if serum glucose <200 mg/dL;
  - albuterol 20 mg with 5-mL saline nebulized over 15 minutes in severe cases with ECG abnormalities refractory to standard treatment.
- Repeat potassium level if ECG normal and hemolysis is suspected.

- Consult nephrology for emergent hemodialysis in all dialysis-dependent patients or those with acute renal failure.

DISPOSITION

Admit all patients with characteristic ECG abnormalities to a monitored setting. All others with potassium levels >6 mEq/L should be admitted, or, in the case of patients with chronic kidney disease, transferred directly to a dialysis unit. For asymptomatic patients without ECG abnormalities suggestive of hyperkalemia with a potassium level <6 mEq/L and an identifiable cause that is not associated with ongoing potassium elevation, discharge with urgent outpatient follow-up is acceptable.

Common Pitfalls

- Failure to recognize and treat ECG abnormalities characteristic of hyperkalemia.
- Failure to consult nephrology for all dialysis-dependent patients.
- Causing volume overload by giving too much $NaHCO_3$ to a patient who is dialysis-dependent or has advanced CHF.

HYPOKALEMIA

CLINICAL PRESENTATION

Hypokalemia is defined by a serum potassium level <3.5 mEq/L. As in patients with hyperkalemia, hypokalemia can present with vague symptoms of muscle weakness, generalized malaise, or paresthesias (2,3,22). Alternatively, even moderate hypokalemia (2.5 to 3 mEq/L) may predispose patients with underlying cardiac disease to life-threatening dysrhythmias and present as cardiac arrest. One unique cause of hypokalemia is hypokalemic periodic paralysis (HPP), which typically presents with recurrent bouts of profound muscular weakness that may progress to respiratory paralysis. Because of the vague presentation and potential for catastrophic sequelae if not detected, all patients who have an underlying disorder, acute illness, or medication profile that predisposes them to hypokalemia and who

present with such symptoms should have a basic electrolyte panel obtained. HPP should be distinguished from the hyperkalemic variety.

DIFFERENTIAL DIAGNOSIS

The most common cause of hypokalemia in ED patients is diuretic-induced renal or diarrhea-induced gastrointestinal losses of potassium. Nonetheless, the finding of low serum potassium should bring to mind a number of other diagnostic considerations (5–7,23–27). Table 211.2 summarizes common causes of hypokalemia in ED patients according to the underlying mechanism of (a) decreased potassium intake, (b) increased potassium loss, or (c) transcellular shifts without total body potassium deficit.

TABLE 211.2
Common Causes of Hypokalemia in Emergency Department Patients

Disorder	Etiology
Inadequate intake	Low dietary content
	Clay ingestion (pica)
Excessive loss	Renal loss
	Diuretics
	Vomiting (contraction alkalosis)
	Hypomagnesemia
	Tubular disorders (type 1 RTA, drugs)
	Renal artery stenosis
	Severe hypertension
	Cushing syndrome
	Primary hyperaldosteronism
	Licorice ingestion
	GI loss (diarrhea)
	Skin loss (profuse sweating, burns)
Transcellular shifts	Metabolic or respiratory alkalosis
	Beta-2 adrenergic stimulation
	Sympathomimetics (cocaine, albuterol)
	Myocardial infarction
	Delirium tremens
	Theophylline
	Thyrotoxicosis
	Exogenous insulin administration
	Endogenous insulin in nondiabetics w/ glucose load
	Barium poisoning
	Hypokalemic periodic paralysis

Thiazide and loop diuretics cause an increased delivery of sodium to the DCT where potassium is lost in exchange as sodium is resorbed. Vomiting and nasogastric suction induce a metabolic alkalosis and selectively decrease chloride. A so-called “chloride-sensitive contraction alkalosis” results leading to an increase in potassium loss at the DCT (2). The mechanism by which hypomagnesemia leads to hypokalemia is unclear but is thought to be related to magnesium’s role as a cofactor for Na/K-ATPase function (3). It is well established that potassium replacement is ineffective if significant hypomagnesemia is not concurrently corrected.

The key effect of transcellular shifts from insulin and beta-2 adrenergic stimulation (albuterol, delirium tremens) was previously covered in this chapter. Overdose with methylxanthines, such as theophylline and caffeine, which are not sympathomimetics, is thought to cause hypokalemia by increasing Na/K-ATPase activity by inhibiting cellular phosphodiesterase or by the attendant hyperadrenergic state accompanying these overdoses (24). Similarly, thyroid storm is often accompanied by hypokalemia as a result of sympathetic outflow combined with a direct effect of increased Na/K-ATPase synthesis. Barium overdose is thought to block potassium's exit from cells (23,26).

Finally, a rare but dramatic presentation of hypokalemia is familial HPP, an autosomal-dominant disorder that results from sudden, rapid shifts of potassium into skeletal muscle. A nearly identical disorder, thyrotoxic periodic paralysis, is the most common form of periodic paralysis reported in Asian populations (25). Both can present with profound muscular paralysis and both respond quickly to IV potassium replacement. Total body potassium stores are normal, so judicious potassium replacement and monitoring are advised to avoid rebound hyperkalemia. Thyroid studies should be obtained in all patients presenting with HPP who are of Asian descent or lack a clear history of familial HPP.

ED EVALUATION

As discussed, a serum potassium level should be obtained in all patients who are acutely ill or who present with vague symptoms of fatigue, weakness, a muscular cramping with any reason to suspect hypokalemia from decreased intake, excess loss, or transcellular shifts as outlined in Table 211.2. Once hypokalemia is detected, a 12-lead ECG should be obtained and the patient maintained on a cardiac monitor if any signs of ectopy are present. A targeted search for the specific causes of the hypokalemia that are outlined in Table 211.2 should be undertaken based on the patient's history and clinical presentation. Along with a standard electrolyte panel, a serum magnesium level should be obtained.

The characteristic ECG abnormalities found in hypokalemia include U-waves, T-wave flattening, and ST-segment depression. Patients with severe hypokalemia (<2.5 mEq/L) or patients with cardiac disease with mild-to-moderate hypokalemia may suddenly develop more severe dysrhythmias—as the relatively hyperpolarized state leads to a prolonged refractory state—predisposing to ventricular fibrillation.

ED MANAGEMENT

The cornerstone of therapy for hypokalemia is potassium replacement and treatment of the underlying cause. Since even mild hypokalemia is often associated with total body deficits of 100 to 200 mEq, replacement is typically slowly over many hours or even days. Though relatively straightforward, the risks of iatrogenic hyperkalemia must be weighed against the need for rapid parenteral replacement. Patients with concomitant hypomagnesemia should have magnesium replaced concurrent with potassium replacement as outlined in Chapter 212.

Most cases of mild-to-moderate (2.5 to 3.5 mEq/L) hypokalemia can be corrected by oral replacement therapy and correction of the underlying cause. Most patients prefer the taste of slow-release tablets compared to liquid preparations, although both wax matrix and microencapsulated formulations carry a slightly increased risk of gastric ulceration (28). A typical oral dose is 40 mEq while in the ED, supplemented with at least 20 mEq daily. Higher daily doses may be needed depending on ongoing losses and dietary supplementation. Patients with hypertension, CHF, or dysrhythmias should ideally have their potassium levels maintained above 4 mEq/L (29). For more severe cases (<2.5 mEq/L) and all cases with cardiac ectopy, profound weakness, ileus, or other severe illness, IV potassium replacement should begin in the ED, and the patient should be admitted to a monitored setting until resolved.

The rate at which potassium can be infused intravenously depends on both the site (peripheral vs. central) and the urgency of the underlying clinical condition (cardiac ectopy, profound muscular weakness, and respiratory depression) for which it is being replaced.

In general, patients with peripheral IV access should not have potassium infused at a rate >20 mEq/hr or 0.2 to 0.3 mEq/kg/hr in children (1,14). In a review of 495 potassium infusion sets of 20 mEq/hr, Kruse and Carlson (30) found a mean increase of 0.25 mmol/L, with only 10 instances of mild hyperkalemia and no temporally related life-threatening dysrhythmias. Though replacement rates of 40 mEq/hr by central line are reported to be safe, this rate should be reserved for cases of severe hypokalemia with sustained, life-threatening cardiac dysrhythmias. In all instances, patients receiving potassium supplementation at rates of 20 mEq/hr or greater should have continuous cardiac monitoring and hourly checks of electrolyte levels.

DISPOSITION

Most cases of mild-to-moderate uncomplicated hypokalemia can be safely discharged with close outpatient reassessment once adequate oral replacement has been initiated. Patients displaying clinical effects of hypokalemia or those with levels <2.5 mEq/L requiring ongoing parenteral correction should generally be admitted.

Common Pitfalls

- Failure to maintain a low threshold for checking potassium levels in all patients who have potential for ongoing potassium loss (diuretic use or diarrhea) or underlying cardiac disease.
- Initiation of potassium replacement therapy before adequate renal function is confirmed.
- Failure to detect and treat concomitant hypomagnesemia.
- Overzealous parenteral potassium replacement, resulting in hyperkalemia, particularly in conditions where hypokalemia is due to transcellular shifts, such as HPP, adrenergic excess, or metabolic alkalosis.
- Inadequate oral replacement for patients with ongoing potassium loss due to diuretic therapy, in whom a minimum of 40 mEq of KCl per day is generally required.

CHAPTER 212

Disorders of Calcium, Phosphate, and Magnesium Metabolism

John W. Love and Robert G. Buckley

OVERVIEW OF CALCIUM METABOLISM

Calcium is a critically important ion. Not only does it comprise the main mineral component of bone, it plays a key role in neuromuscular transmission and serves as a cofactor in numerous extracellular and intracellular processes. Serum calcium levels are tightly regulated within a normal range of 8.5 to 10.5 mg/dL or an ionized level of 1.0 to 1.15 mmol/L. Roughly half of serum calcium is protein-bound, and half is the form of physiologically active free ionized calcium (1–4).

Parathyroid hormone (PTH) is the key controller of serum calcium concentration. As calcium levels fall, PTH is secreted from the four tiny parathyroid glands in the anterior neck, leading to a rapid increase in calcium resorption from bone and reabsorption in the distal renal tubules (5,6). PTH also stimulates renal production of 1,25-dihydroxyvitamin D that leads to increased absorption of calcium in the gut. Rising calcium levels lead to a decrease in PTH release with subsequent calcium bone deposition, renal excretion, and diminished gastrointestinal (GI) uptake (3,6).

HYPERCALCEMIA

CLINICAL PRESENTATION

Hypercalcemia is defined as a serum calcium concentration of >10.5 mg/dL. The signs and symptoms of mild hypercalcemia (up to 12 mg/dL) are generally vague and include changes in cognitive function, depression, and fatigue (1,7). Higher levels are more frequently associated with GI symptoms (nausea, anorexia, constipation, and abdominal pain), muscle weakness, and more profound changes in mental status. The electrocardiograph (ECG) may reveal QT_c shortening and PR or QRS widening (3). As with other electrolyte abnormalities, the nonspecific nature of the clinical presentation calls for a low threshold in ordering calcium levels. Hypercalcemic crisis may occur when levels reach 14 mg/dL or greater, resulting in paralysis or coma (1,3,7).

DIFFERENTIAL DIAGNOSIS

Although a number of disorders lead to hypercalcemia (Table 212.1), the most common cause in ambulatory patients is primary hyperparathyroidism, which is often detected during laboratory screening of asymptomatic or minimally symptomatic patients. In hospitalized patients, cancer is the most common etiology (3,7). Humoral hypercalcemia of malignancy is due to tumors secreting PTH-related protein (e.g., squamous cell carcinomas) or calcitriol (e.g., B-cell lymphomas). A separate mechanism of hypercalcemia in cancer patients is due to local osteolytic hypercalcemia that occurs when tumor within the bone itself (e.g., multiple myeloma) causes cytokine release and increased osteoclastic calcium resorption from bone (7). Other causes such as granulomatous disease (e.g., sarcoidosis), medications (e.g., lithium and thiazide diuretics), endocrine disorders, or factious hypercalcemia should also be considered (1,3,7).

TABLE 212.1
Causes of Hypercalcemia

Hyperparathyroidism (e.g., adenoma, hyperplasia, or carcinoma)
Malignancy-associated hypercalcemias
Humoral hypercalcemia of malignancy (e.g., squamous cell carcinomas of lung, oropharynx, kidney, cervix, or ovary)
Local osteolytic hypercalcemia (e.g., multiple myeloma, breast cancer, or lymphoma)
Granulomatous diseases (e.g., sarcoidosis, tuberculosis, or histoplasmosis)
Medications (e.g., vitamin A or D supplements, antacids, lithium, or thiazide diuretics)
Factitious hypercalcemia (e.g., hyperproteinemias)
Thyrotoxicosis
Adrenal insufficiency

ED EVALUATION

Once an elevated calcium level has been detected, the serum protein or albumin level should be measured. The "corrected" level of calcium is obtained by lowering the measured serum concentration by 0.8 mg/dL for every 1 g/dL of protein or albumin above the normal reference range (e.g., multiple myeloma). Alternatively, an ionized calcium level can be quickly obtained from most arterial blood gas analyzers (1,3,6–8).

Because hypercalcemia is associated with a number of malignancies, granulomatous diseases, endocrinopathies, and medications, further investigation to detect these disorders should be initiated in the emergency department (ED) based on accompanying clinical findings. At a minimum, a complete blood count, comprehensive metabolic panel (to include magnesium and phosphate levels and renal and liver function studies), urinalysis, ECG, and chest radiography should be obtained in all patients. The most important next step in investigating hypercalcemia in a patient without an obvious neoplastic etiology is to obtain a serum PTH concentration. This is generally best coordinated with the primary provider following up the ongoing care of the patient (1,3,6).

ED MANAGEMENT AND DISPOSITION

Most cases of mild or even moderate hypercalcemia in an otherwise well-hydrated, minimally symptomatic patient require no immediate

ED treatment. Those with more profound symptoms and higher levels—typically found in patients with known malignancy—should have treatment to lower calcium levels initiated in the ED and be admitted.

Virtually all cases of severe hypercalcemia are associated with some degree of volume contraction. Therefore, the first step is to give at least 1 L of normal saline to reexpand the extracellular space. After the volume status has been corrected with 1 to 2 L of normal saline, furosemide 40 mg IVP should be given to enhance calcium excretion (1,3,6).

Repeat electrolyte and calcium levels should be obtained roughly 2 hours after initiating ED treatment and generally show a decrease in the serum calcium level by 1 to 2 mg/dL. Patients who fail to respond adequately to IV hydration and diuresis should have further therapy aimed at decreasing calcium mobilization (1,3,6). Bisphosphonates (pamidronate 60 to 90 mg IVPB over 4 hours or zoledronate 4 mg IVPB over 15 minutes) are the mainstay of treatment for cancer-related hypercalcemia (7). Alternative therapies such as mithramycin (25 μg/kg over 4 hours), which directly inhibits osteoclastic activity, or calcitonin (4 IU subcutaneously or IM), which has the most rapid onset, are both limited by a higher incidence of side effects. Glucocorticoids (e.g., hydrocortisone 200 mg IV or its equivalent) are beneficial in patients with hematologic cancers, granulomatous diseases, or vitamin D toxicity but are ineffective in nonhematologic tumors or parathyroid adenomas (7).

Patients with symptomatic hypercalcemia require admission for IV fluids, parenteral therapy, and careful monitoring of fluid status. Minimally symptomatic or asymptomatic patients with mild to moderate hypercalcemia (corrected calcium level <13.0 mg/dL) and no known malignancy should have a PTH level ordered and close outpatient follow-up arranged.

CRITICAL INTERVENTIONS

- Measure a calcium level in all patients with known or suspected malignancy who present with fatigue, weakness, or change in mental status.
- Treat all cases of hypercalcemia with profound fatigue, muscle weakness, altered mental status, cardiac dysrhythmias, or serum calcium level of 14 mg/dL or greater.
- Restore the intravascular volume with 1 to 2 L of normal saline before initiating loop diuretic therapy.

Common Pitfall

- Failure to repeat serum calcium levels 2 hours after initiation of treatment to gauge effectiveness.

HYPOCALCEMIA

CLINICAL PRESENTATION, DIFFERENTIAL DIAGNOSIS, AND ED EVALUATION

Hypocalcemia is generally defined by a serum calcium level <9 mg/dL, with severe hypocalcemia defined as serum calcium ≤ 7.0 mg/dL. Neuromuscular irritability is the hallmark of true hypocalcemia. Tetany, muscle cramps, and spasms commonly ensue at adjusted corrected calcium levels <7.5 mg/dL. In extreme cases, cyanosis from glottic and diaphragmatic spasm can ensue (2,3,6).

The two classic physical findings of hypocalcemia, Chvostek and Trousseau signs, when present, are useful in corroborating the presence of ionized hypocalcemia (2–4,6). Chvostek sign is facial musculature twitching elicited by percussion over the facial nerve in the preauricular region. Trousseau sign is carpal spasm after inflation of a brachial blood pressure cuff above the patient's systolic blood pressure for 3 minutes. Unfortunately, neither sign has adequate accuracy to detect or completely exclude significant hypocalcemia. Therefore, as with almost all electrolyte disorders, a low threshold for obtaining calcium levels should be maintained

when evaluating patients with neuromuscular abnormalities or complaints.

The concentration of bioactive calcium is best obtained by measuring an ionized calcium level, which can be obtained from most blood gas analyzers (8). If the ionized calcium level cannot be obtained, then measure the serum calcium and albumin concentrations. Calculate the corrected calcium level by adding 0.8 mg/dL to the serum calcium level for each decrease of 1 g/dL of serum albumin <4 g/dL. The corrected QT interval is characteristically prolonged in hypocalcemia and may rarely progress to ventricular dysrhythmias, such as torsades de pointes, or heart block (3,6).

Although the most common cause of a low serum calcium level is pseudohypocalcemia due to reduced serum protein states, a number of causes should be considered when a true reduction in ionized calcium is encountered (Table 212.2). The vast majority of cases of true hypocalcemia are due either to an insufficiency in the production or bio-effectiveness of either PTH or vitamin D metabolites (2,3,6). Additionally, symptomatic hypocalcemia can be found in a number of disease states in which chelation with organic anions leads to decreased ionized calcium levels (6). Examples include hyperphosphatemia in rhabdomyolysis, saponification with fatty acids in severe pancreatitis, and citrate chelation with massive transfusion of preserved blood products. Hypocalcemia is well reported in severe hydrofluoric acid burns and is generally considered secondary to precipitation of calcium fluoride, though the precise mechanism remains under investigation (3,9). Alkalosis increases calcium binding to plasma proteins and can lead to a decreased ionized calcium level despite the presence of a normal serum calcium level—a common result of tetany in acute hyperventilation (3,6).

TABLE 212.2
Causes of Hypocalcemia

Parathyroid Hormone Insufficiency
Iatrogenic (e.g., surgical or radiation)
Infiltrative (e.g., hemochromatosis, Wilson disease)
Autoimmune
Magnesium deficiency
PTH resistance

Vitamin D Insufficiency
Nutritional deficiency (e.g., rickets, osteomalacia)
Malabsorption (e.g., gastrectomy, inflammatory bowel disease)
Altered vitamin D metabolism (e.g., hepatic or renal disease)

Medications
Bisphosphonates
Phosphates (e.g., cow's milk hypocalcemia in neonates)
Calcitonin
Plicamycin

Other Conditions
Pseudohypocalcemia (e.g., hypoalbuminemic states)
Acute pancreatitis
Rhabdomyolysis
Tumor lysis syndrome
Massive transfusion of citrated blood
Osteoblastic metastases (e.g., breast or prostate cancer)
Neonatal hypocalcemia (high phosphate cow's milk)
Ethylene glycol poisoning (due to calcium oxalate precipitation)
Hydrofluoric acid burns

ED MANAGEMENT AND DISPOSITION

Treatment with IV calcium salts should be initiated immediately in all patients with neuromuscular excitability and true hypocalcemia (adjusted for serum albumin or from direct measurement of ionized calcium). The goal of therapy is to eradicate all signs or symptoms of neuromuscular excitability by attaining a serum calcium level of roughly 8 to 9 mg/dL. To do this, an initial dose of 200 to 300 mg of elemental calcium should be slowly infused over 5 to 10 minutes while the patient is maintained on a cardiac monitor (2,3,6).

Either calcium chloride 10% (360-mg calcium per 10-mL ampule) or calcium gluconate 10% (93-mg per 10-mL ampule) may be used

(10,11). However, calcium chloride much more commonly leads to localized pain and thrombophlebitis at the infusion site and, thus, should only be used peripherally if calcium gluconate is not available. Repeat boluses or an infusion rate of 0.5 to 2.0 mg/kg/hr of elemental calcium may be required if symptoms recur (3,6). For infants and young children, the recommended initial dose of calcium gluconate 10% is 0.5 to 1.0 mL/kg (3).

Parenteral calcium administration should be performed with extra care in patients taking digoxin, owing to a proarrhythmic effect that has been reported (2,3). Calcium salts should never be given through the same infusion site as sodium bicarbonate owing to precipitation of calcium bicarbonate. Patients with concomitant hypomagnesemia should have magnesium replaced as outlined later in this chapter. Repeat calcium and magnesium levels should be obtained every 1 to 2 hours.

All patients requiring ongoing parenteral calcium replacement should be admitted to a monitored setting. Those patients with minimal associated symptoms and without QT prolongation can generally be discharged with early outpatient follow-up. The decision to initiate supplemental oral calcium and vitamin D therapy, as well as further specific diagnostic testing, is best made in concert with the patient's primary provider prior to discharge.

CRITICAL INTERVENTIONS

- Exclude pseudohypocalcemia by confirming the ionized calcium level or adjusting the serum calcium level for hypoproteinemia.
- Obtain a 12-lead ECG to rule out QT_c prolongation, particularly in patients with underlying heart disease.
- Infuse one 10-mL ampule of calcium gluconate over 2 minutes in symptomatic patients with confirmed hypocalcemia, repeating up to three doses and initiating a continuous infusion if the patient has persistent or recurrent symptoms.
- Measure and replace magnesium when the serum magnesium level drops below 1.0 mEq/L.

Common Pitfall

- Do not rely on the absence of Chvostek and Trousseau signs to exclude the possibility of hypocalcemia. Obtain serum calcium levels on patients suspected of having hypocalcemia.

PHOSPHORUS METABOLISM

Phosphate is a crucial substance for all cells, forming a major component in phospholipid cell membranes and in high-energy compounds such as adenosine triphosphate. Roughly 85% of the body's phosphorous is stored in bones as hydroxyapatite and is controlled by PTH and vitamin D similar to calcium. The recommended daily allowance is 800 mg, which is found in high concentrations in meats and dairy products. More than 90% is renally excreted. The normal range of serum phosphate is 2.5 to 4.5 mg/dL (6).

Isolated phosphorous abnormalities requiring treatment in the ED are exceedingly rare. Nonetheless, a basic understanding of phosphorous abnormalities remains important for EM practice, as mild to moderate abnormalities are fairly regularly encountered particularly in patients with diabetes, alcoholism, cancer, chronic obstructive pulmonary disease (COPD), and renal failure. Furthermore, severe abnormalities occasionally present needing immediate intervention (12).

HYPERPHOSPHATEMIA

CLINICAL PRESENTATION, DIFFERENTIAL DIAGNOSIS, AND ED EVALUATION

Mild to moderate hyperphosphatemia is defined by levels roughly between 5 and 14 mg/dL and is generally asymptomatic. Levels above 14 mg/dL or those with symptoms associated with hypocalcemia (as previously described) define severe hyperphosphatemia (12).

Hyperphosphatemia is most commonly encountered in patients with chronic renal failure but may also be found in hypoparathyroid states, after excess exogenous administration, or owing to cell breakdown in rhabdomyolysis, cancer, or hemolysis (3,6,13). Pseudohyperphosphatemia results from inorganic phosphate measurement during laboratory analysis in cases such as multiple myeloma, hyperlipidemia, hemolysis, and hyperbilirubinemia. Evaluation of hyperphosphatemia is generally directed at the underlying cause and associated hypocalcemia. Calculation of the calcium–phosphate product (serum calcium multiplied by serum phosphorous) is an important step, as values >70 are associated with accelerated myocardial, vascular, and other soft-tissue calcification.

ED MANAGEMENT AND DISPOSITION

Treatment of hyperphosphatemia rarely needs to be initiated in the ED. Emergency treatment, rather, is directed at the accompanying hypocalcemia, as previously described.

Patients with normal renal function, who have hyperphosphatemia from exogenous sources (such as rhabdomyolysis), generally respond to saline diuresis. Patients with renal failure with moderate phosphate elevation or whose calcium–phosphate product exceeds 70 are usually managed as outpatients with a diet low in protein and dairy products and with calcium- or aluminum-containing phosphate binders (6,13). Dialysis is only transiently effective in lowering serum phosphate levels and should be reserved for overtly symptomatic patients with reduced renal function (3,6,13).

HYPOPHOSPHATEMIA

CLINICAL PRESENTATION, DIFFERENTIAL DIAGNOSIS, AND ED EVALUATION

Hypophosphatemia is a relatively common finding, with a prevalence of roughly 1% to 3% in unselected hospitalized

populations. Moderate hypophosphatemia is defined by a serum phosphate concentration of 1.0 to 2.5 mg/dL. Symptoms generally are manifest only with severe hypophosphatemia, defined as levels <1.0 mg/dL (12). As phosphate is a cardinal element in cellular metabolism for processes such as oxidative phosphorylation and glycolysis, symptoms related to impaired skeletal and myocardial muscle function are most common. In addition, hypophosphatemia can decrease 2,3-diphosphoglycerate (2,3-DPG) in red blood cells which leads to a decrease in hemoglobin oxygen release, most importantly in the myocardium and central nervous system, which may lead to signs of encephalopathy and coma (6).

The differential diagnosis of hypophosphatemia, shown in Table 212.3, is grouped according to the underlying mechanism: renal loss, decreased absorption, or transcellular shifts of phosphate into the cell. Hypophosphatemia is common in chronic alcoholics, with a prevalence of up to 50% in admitted Veteran's Administration hospitals (11). As with hypokalemia, patients with diabetic ketoacidosis almost universally have some degree of phosphate depletion owing to extracellular shifts and osmotic renal losses and initially present with normal phosphate levels that rapidly decrease as phosphate shifts intracellularly once insulin is administered (14). All disease states presenting with alkalosis or catecholamine excess can have some degree of hypophosphatemia (3,11).

TABLE 212.3
Causes of Hypophosphatemia

Renal Loss
Renal tubular dysfunction
Diuretic therapy
Hyperosmotic states (DKA, HONK hyperglycemia)
Hyperparathyroidism
Decreased Intake
Malnutrition (e.g., alcoholism)
Phosphate-binding antacids
Chronic diarrhea
Inflammatory bowel disease
Vitamin D deficiency
Transcellular Shifts
Respiratory alkalosis (COPD, sepsis, ASA poisoning)
Hyperadrenergic states (Etoh withdrawal)
Hyperglycemia
Insulin therapy

ASA, acetylsalicylic acid; COPD, chronic obstructive pulmonary disease; DKA, diabetic ketoacidosis; HONK, hyperosmolar nonketotic coma.

ED MANAGEMENT AND DISPOSITION

Phosphate replacement rarely needs to be initiated in the ED. Intravenous replacement therapy is almost never needed in the ED and is only necessary for patients with profound muscle weakness, respiratory insufficiency, or myocardial dysfunction or those patients with a serum phosphate level <1.0 mg/dL (11,15). The typical infusion rate for IV replacement calls for no more than 1 g of elemental phosphate infused over a 24-hour period (11,15). (One millimole of phosphate is equivalent to 31 mg of elemental phosphorous.) An acceptable rate to initiate in the ED is 4.5 mmol/hr for the first 3 hours, and phosphate should never be infused with lactated Ringer owing to precipitation with calcium. Patients receiving IV replacement should be monitored for tetany from attendant hypocalcemia or hypotension. All patients requiring IV replacement of phosphate should be admitted.

Asymptomatic patients with mild to moderate hypophosphatemia can be treated orally as outpatients with sodium phosphate (Neutra-Phos) or, in patients with concomitant hypokalemia, as in diabetic

ketoacidosis, with potassium phosphate (K-Phos). The typical dose is one 250 mg capsule four times daily (12).

CRITICAL INTERVENTIONS

- Measure serum phosphate levels in groups who are at high risk for hyperphosphatemia (renal failure, malignancy, severe rhabdomyolysis), hypophosphatemia (alcoholism, diabetic ketoacidosis, COPD, sepsis), or coexisting electrolyte, calcium, or magnesium abnormalities
- Initiate treatment for hyperphosphatemia only when the level exceeds 14 mg/dL; direct treatment at the underlying cause
- Initiate IV phosphate therapy only for symptomatic patients with serum phosphate levels <1.0 mg/dL—all others may have phosphate replaced orally

Common Pitfalls

- Failure to recognize, initiate treatment, and obtain close follow-up for renal failure patients with a calcium–phosphate product >70. These patients are at long-term risk for accelerated calcium deposition in vital organs, arteries, and soft tissues.
- Failure to recognize that serum phosphate levels may drop precipitously once patients with malnutrition (e.g., alcoholics receiving glucose therapy) or acidosis (diabetic ketoacidosis patients receiving IV insulin therapy) are treated.
- Failure to monitor patients receiving IV phosphate therapy for hypotension or tetany owing to accompanying acute hypocalcemia.

MAGNESIUM METABOLISM

Magnesium is the second most abundant intracellular cation. It is involved in numerous physiologic processes, including cardiac and neural depolarization, energy storage, nucleic acid stability, and enzyme activation (16). The average healthy adult contains approximately 25 g of magnesium. Of this amount, 50% is complexed in bones and not readily exchangeable, whereas 49% is

distributed to the intracellular soft-tissue space. Only 1% of body stores are found in the extracellular space and are thus available to be detected by routine electrolyte laboratory testing (6). Despite the fact that total serum levels are an insensitive determination of actual body magnesium stores, they remain the clinically most common standard for defining magnesium status. Normal plasma concentrations range from 1.8 to 2.5 mg/dL.

In contrast to sodium, potassium, and calcium, there is little evidence suggesting direct hormonal control of magnesium homeostasis. Instead, magnesium balance is the result of intestinal absorption, obligatory secretion, and renal excretion. The average adult consumes 250 to 300 mg of magnesium per day. Under normal conditions, net absorption by the intestine is approximately 100 mg/d via a saturable transport system and passive diffusion process, regardless of serum levels. In contrast, the kidney adjusts the rate of magnesium excretion depending on serum levels. Under normal conditions, the kidney excretes approximately 5% (100 mg) of the filtered load per day and can decrease the excreted amount to 0.5% or increase it to 80% of the filtered load. Hypermagnesemia develops during renal failure because of the lack of a feedback mechanism to regulate intestinal absorption. Hypomagnesemia occurs with prolonged poor dietary intake, malabsorption syndromes, or renal wasting, despite renal compensatory mechanisms (1,3,7).

HYPERMAGNESEMIA

CLINICAL PRESENTATION, DIFFERENTIAL DIAGNOSIS, AND ED EVALUATION

Hypermagnesemia is uncommon in the ED in the absence of renal insufficiency or treatment for preeclampsia. As such, most cases of hypermagnesemia can be anticipated. During acute renal failure, hypermagnesemia develops because intestinal absorption continues despite elevated serum magnesium levels. Many over-the-counter medications contain a significant amount of magnesium,

particularly antacids and laxatives. Renal failure patients should not receive inappropriate medications containing magnesium. Nonrenal risk factors associated with hypermagnesemia include advanced age, the misuse of magnesium-containing medications, and narcotic or anticholinergic medications, which decrease GI tract motility and enhance magnesium absorption. The typical hypermagnesemic patient with normal renal function is an elderly individual taking a narcotic or anticholinergic medication with a history of laxative use for constipation (3,6,17). Several pediatric fatalities from the inappropriate use of over-the-counter magnesium-containing medications have been reported.

Hypermagnesemia results in neuromuscular depression by inhibiting acetylcholine release at the neuromuscular junction (18). In addition, magnesium acts as a calcium-channel blocker and can impair cardiovascular function. Common initial ECG findings include PR and QRS interval prolongation. Symptoms are unusual until the serum magnesium level exceeds 4 mg/dL. A serum magnesium level is diagnostic. Initially, the presentation is nonspecific and includes nausea, vomiting, and weakness. As the serum magnesium level increases above 7 mg/dL, loss of deep-tendon reflexes, muscle paralysis, respiratory insufficiency, and cardiac arrest may occur.

ED MANAGEMENT AND DISPOSITION

In the mildly symptomatic patient with normal renal function, discontinuing the additional magnesium alone will rapidly result in normal serum levels, although GI tract decontamination may be needed to prevent ongoing absorption in magnesium oxide overdose (17). Renal excretion is enhanced by first expanding the extracellular space with IV fluids followed by furosemide 40 mg IVP. Treatment with IV calcium can rapidly reverse the calcium-channel blocking effect from severe magnesium toxicity. Use either 5 to 10 mL of calcium chloride 10% or one to two 10-mL ampules of calcium gluconate 10% over 5 minutes. The pediatric dose of calcium gluconate 10% is 0.5 to 1.0 mL/kg (3,6). The ECG and

hemodynamic parameters should guide repeat IV calcium therapy. Peritoneal dialysis or hemodialysis with a low-magnesium dialysate is also very effective in decreasing toxic serum magnesium levels. Finally, transvenous cardiac pacing has been reported to be effective in hypermagnesemic asystole that is refractory to calcium chloride (19).

CRITICAL INTERVENTION

- Administer IV calcium to counter the effects of severe hypermagnesemia.

Common Pitfalls

- Failure to remember that renal failure is the main risk factor for developing hypermagnesemia.
- Failure to consider hypermagnesemia in symptomatic elderly patients taking magnesium-containing laxatives.

HYPOMAGNESEMIA

CLINICAL PRESENTATION, DIFFERENTIAL DIAGNOSIS, AND ED EVALUATION

Magnesium deficiency can be categorized into three main areas: increased losses either renal or intestinal, inadequate intake, or cellular redistribution. Table 212.4 lists the most common specific causes. Hypomagnesemia is routinely encountered in the ED and is defined as a total serum magnesium concentration of <1.5 mg/dL. It rarely occurs as an isolated metabolic abnorm-ality as the predisposing conditions also lead to other electrolyte imbalances (3,6).

TABLE 212.4
Causes of Hypomagnesemia and Magnesium Deficiency

Increased Losses	Gitelman syndrome
Intestinal	Bartter syndrome
Diarrhea	Dietary
Laxatives	Chronic alcoholism
Malabsorption syndromes	Anorexia nervosa
Inflammatory bowel disease	Malnutrition
Short bowel syndrome	**Redistribution**
Renal	Metabolic acidosis
Drugs	Insulin (DKA)
Loop diuretics	Acute pancreatitis
Aminoglycosides	Parathyroidectomy/hungry bone syndrome
Amphotericin B	Refeeding syndromes after starvation
Cisplatinum	**Miscellaneous**
Cyclosporine	TPN
Pentamidine/Foscarnet	Hyperthyroidism
Tubular defects	Cardiopulmonary bypass
Osmotic diuretics (glycosuria)	Diabetes
Diuretic phase of ATN	
Postobstructive diuresis	
Ethanol	

ATN, acute tubular necrosis; DKA, diabetic ketoacidosis; TPN, total parenteral nutrition.

Severe symptomatic hypomagnesemia depends on the rate of development but is rare unless serum levels are below 1.0 mg/dL. Predisposing conditions that lead to hypomagnesemia include chronic alcoholism, diuretic use, and renal toxic drugs such as cisplatinum. The most common clinically recognizable manifestations are cardiac dysrhythmias and neuromuscular irritability, similar to those described for hypocalcemia. The most immediate life-threatening concern is ventricular dysrhythmias, particularly torsades de pointes. Predisposing conditions include myocardial ischemia and QT/QT_c prolongation, regardless of cause. Common ECG changes are similar to those encountered in hypocalcemia and hypokalemia. Neuromuscular symptoms include ataxia, tetany, and seizures (3,6,15).

ED MANAGEMENT AND DISPOSITION

All patients with symptomatic magnesium deficiency require immediate IV access, an ECG, and continuous cardiac monitoring. The initial focus is to prevent and stabilize cardiac dysrhythmias (10). Current Advanced Cardiac Life Support guidelines consider IV magnesium as the antidysrhythmic of choice for torsades de pointes or ventricular fibrillation–pulseless ventricular tachycardia in the known or suspected hypomagnesemic patient. The recommended adult dose for life-threatening dysrhythmias or severe neuromuscular symptoms is 2 g IV over 30 to 60 seconds (25 to 50 mg/kg in children, 2 g maximum). The rate of infusion should be slowed for less severe conditions. Side effects depend on the rate of infusion and include flushing, bradycardia, hypotension, and dysrhythmias. After the appropriate clinical response, follow up the bolus with a continuous infusion of 0.5 to 1 g/hr for several hours in patients with normal renal function. It is important to note that the kidneys will excrete the majority of the administered IV magnesium. Although serum levels will rapidly normalize, total body intracellular stores require several days to correct. Loss of deep-tendon reflexes and progressive weakness are early clinical indicators of magnesium toxicity.

Magnesium has been extensively studied in the treatment of acute myocardial infarction (AMI). Proposed theoretical benefits include an antidysrhythmic effect, limiting the influx of calcium into ischemic myocytes, and decreasing vascular smooth muscle tone. Several early small trials supported the use of IV magnesium as an adjuvant treatment for AMI. The ISIS-4 and Magnesium in Coronaries trial studied more than 64,000 patients with suspected AMI and IV magnesium initiated after reperfusion therapy. The study, the largest prospective investigation to date, found no benefit for mortality or dysrhythmias in the magnesium group, indicating no clear routine role for magnesium in the treatment of AMI. Moreover, the Intravenous Magnesium for Acute Myocardial Infarction Cochrane meta-analyses review included 26 previous clinical trials, and concluded that it is unlikely that magnesium is beneficial in reducing mortality. Magnesium may reduce the incidence of severe arrhythmias needing treatment, but it may

increase the incidence of profound hypotension, bradycardia, and flushing. The evidence does not support the use of IV magnesium in the treatment of AMI (20).

Animal studies indicate that IV magnesium has a relaxant effect on smooth muscle and acts as a bronchodilator, and early human clinical trials suggested that IV magnesium could produce additional bronchodilation when added to standard asthma treatment. A meta-analysis from the Cochrane Airway Review Group concluded that current evidence does not support the routine use of IV magnesium in ED patients presenting with mild to moderate asthma exacerbations, but subgroup analyses in the severe asthmatic group revealed a decreased admission rate and a small improvement in peak expiratory flow rate. The absolute FEV_1 improved by 10% of predicted. The authors concluded that magnesium appears to be safe and beneficial for patients who present with severe acute asthma (17). Adult study participants received magnesium 1.2 to 2 g IV over 20 minutes after standard albuterol therapy. In the pediatric studies, children received 25 or 100 mg/kg (maximum 2 g) IV over 20 minutes (21).

Magnesium is also used in several other clinical scenarios. Decades of experience support the use of magnesium in preeclamptic and eclamptic patients. Magnesium deficiency is a common finding in chronic alcoholism and alcohol withdrawal. Although IV replacement in the ED is a common practice, routine parenteral administration of magnesium is not recommended because existing controlled data do not demonstrate improvement in alcohol withdrawal severity, delirium, or seizures (22).

CRITICAL INTERVENTIONS

- Place patients with suspected hypomagnesemia on a cardiac monitor and perform an ECG.
- Administer IV magnesium for patients with dysrhythmias (torsades de points) due to magnesium deficiency.

Common Pitfalls

- Total magnesium serum levels are an inaccurate indicator of actual intracellular body stores.
- Failure to appreciate that predisposing conditions that lead to magnesium deficiency commonly lead to other electrolyte abnormalities.
- The kidneys rapidly excrete the majority of an IV magnesium bolus, while replenishing body stores takes days.

CHAPTER 213
Rhabdomyolysis

Mark T. Steele

Rhabdomyolysis is a clinical syndrome resulting from injury to skeletal muscle. The most common causes in hospitalized adults are alcohol and drugs (illicit and prescribed), followed by muscle diseases, muscle trauma, neuroleptic malignant syndrome, seizures, immobility, metabolic, infection, exercise, and heat-related causes (Table 213.1) (1–3). It is common for there to be multiple causes of a given episode. Viral myositis and trauma are the most common etiologies in the pediatric age group (4). The final common pathway of all these etiologies is damage to the muscle cell membrane, or sarcolemma, which results in an influx of calcium and the liberation of intracellular contents such as creatine, myoglobin, **alanine aminotransferase, aspartate aminotransferase,** lactate dehydrogenase (LDH), aldolase, potassium, uric acid, and phosphorus (2).

Idiopathic

CLINICAL PRESENTATION

The presenting symptoms and signs of rhabdomyolysis are variable and generally reflect the underlying cause. The classic triad of muscle weakness, tenderness, and swelling is uncommon. Symptoms may be vague or absent in up to 50% of patients with rhabdomyolysis. About half of the patients in one series had muscle pains primarily involving the thighs, calves, and lower back (1). The physical examination is likewise often of limited value in making the diagnosis. In a pediatric cohort of patients, 45% complained of muscle pain and about 40% had a fever and symptoms of viral infection (5).

Because the history and physical examination can be nonspecific, a high index of suspicion should be maintained, particularly in the setting of seizures, unconsciousness, or agitation. The prehospital history may be helpful, particularly if the patient has an altered mental status: There may be a history of suspected overdose, seizure, or prolonged immobilization. There may also be a history of drug abuse or recent strenuous exercise or a family history of muscle dysfunction. The history should also include current medical problems and medications, any recent trauma or compression, bites and stings, infections, excessive exertion, electrical shock, or temperature extremes. Rarely, patients may report that their urine is dark reddish-brown (port-wine–like color). This symptom can occur if myoglobin levels exceed 100 mg/dL (1).

The major complications of rhabdomyolysis are listed in Table 213.2. Hyperkalemia is the most serious complication, because it can result in cardiac arrest and death if not diagnosed and treated promptly, particularly following crush-related disasters like earthquakes (6,7).

TABLE 213.2
Major Complications of Rhabdomyolysis

Hyperkalemia/cardiac dysrhythmias
Acute renal failure
Compartment syndrome
Disseminated intravascular coagulation
Respiratory dysfunction

Hyperphosphatemia, hypocalcemia, hyperuricemia, and hypoalbuminemia are also potential complications. Hypocalcemia, the most commonly encountered metabolic abnormality, is believed to be caused by calcium entering damaged muscle cells and from deposition of calcium phosphate in necrotic muscle (2). Hyperuricemia is related to the release of intracellular purines from damaged muscle tissue, and hypoalbuminemia is related to leakage of protein from injured muscle vessels. Release of organic acids from dying muscle cells may produce an elevated anion gap metabolic acidosis.

Acute renal failure is a major complication of rhabdomyolysis, with the reported incidence ranging from 4% to nearly 50% in retrospective studies (1,2,8,9). In an undifferentiated population of pediatric patients the rate of acute renal failure was 5% (5); the incidence was 13% in a pediatric trauma patient population (10). There are no well-designed prospective studies, so the true incidence of acute renal failure is unknown. In this setting, there is decreased glomerular filtration rate (GFR), the exact mechanism of which is unclear. Experimental evidence suggests increased renal vascular resistance secondary to intrarenal vasoconstriction, which may be due to microthrombi, activation of the renin–angiotensin system, vasopressin, or prostaglandins. Cellular release of myoglobin can lead to tubular obstruction and leakage of free radicals which also can cause cellular damage (2). The exact role of myoglobin is unclear, but it is known that hypovolemia and acid urine are required for myoglobin to result in renal injury. Likely predictors of renal failure in rhabdomyolysis include the degree of elevation of serum creatine phosphokinase (CPK) and the presence of sepsis or dehydration (3).

Compartment syndrome may be either a cause or a complication of rhabdomyolysis. In the latter case, this is more likely to occur in the setting of crush injuries (1). Fluid accumulates in the interstitial space, resulting in swelling and an increased intracompartmental pressure, leading to further muscle damage and necrosis. Compartment syndrome should be anticipated in patients with rhabdomyolysis, and compartment pressures measured if it is suspected. Fasciotomy should be strongly considered in patients with pressures >35 mm Hg.

There are other potential complications. Disseminated intravascular coagulation (DIC) is believed to be the result of the liberation of activating substances such as thromboplastin from necrotic muscle. Respiratory dysfunction can occur as a result of involvement of the respiratory musculature. Myocardial damage can also occur, resulting in manifestations ranging from isolated electrocardiographic (ECG) changes to heart failure and death (1).

DIFFERENTIAL DIAGNOSIS

Rhabdomyolysis should be considered in patients with muscle injury (direct trauma, burns, or compartment syndrome), known muscle disease, or exceptional muscular activity. Besides overt trauma, rhabdomyolysis can be seen in comatose patients or anesthetized surgical patients who remain in the same position for a prolonged period of time. In addition, rhabdomyolysis must always be part of the differential diagnosis of acute renal failure.

Drugs and toxins (Table 213.3) are the most common causes of rhabdomyolysis in adults. Ethanol, the most commonly implicated of these, has a direct toxic effect on the muscle cell membrane. More importantly, severe intoxication with alcohol or sedative–hypnotic drugs can result in prolonged immobilization and compression of the extremities, with resulting compromise of the blood supply to muscle. Metabolic complications of alcoholism, such as hypokalemia, hypophosphatemia, and hypomagnesemia, may also increase the risk of rhabdomyolysis. Alcohol-withdrawal seizures and delirium tremens can cause excessive muscular activity, with resultant rhabdomyolysis (11).

TABLE 213.3
Drug- and Toxin-Associated Rhabdomyolysis

Drugs of Abuse

Amphetamines/methamphetamine
Bath salts (mephedrone or methylenedioxy pyrovalerone [MDPV])
Barbiturates/sedative hypnotics
Cocaine
Lysergic acid diethylamide (LSD)
Opioids
Phencyclidine hydrochloride (PCP)

Alcohols

Ethanol
Ethylene glycol
Isopropyl alcohol
Methanol

Psychiatric Drugs

Antipsychotics
Lithium
Antidepressants (all classes)

Antiretrovirals

Didanosine
Lamivudine
Tenofovir
Zidovudine
Integrase inhibitors (e.g., Raltegravir)
Maraviroc

Anesthetics/Neuromuscular Blocking Agents

Inhaled gases (e.g., halothane)
Ketamine
Propofol
Succinylcholine

Antihistamines

Diphenhydramine
Doxylamine

Sympathomimetics (e.g., phenylpropanolamine)

Lipid-Lowering Agents

Statins
Fibric acid derivatives (fibrates)
Niacin

Other Drugs

Acetaminophen
Amiodarone
Amphotericin B
Anticholinergics
Azathiopine
Baclofen
Colchicine
Cyclosporine
Cyclobenzaprine
Daptomycin
Diuretics
Epsilon aminocaproic acid
Erythromycin
Glucocorticoids and anabolic steroids
Isoniazid
Laxatives
Leflunomide
Linezolid
Phenytoin
Promethazine
Proton-pump inhibitors
Quinidine
Salicylates
Terbutaline
Theophylline
Trabectedin
Trimethoprim sulfamethoxazole
Valproic acid
Vasopressin

Other Toxins

Arsenic
Carbon monoxide
Toluene
Mercuric chloride
Quail eating
Haff disease
Wild mushrooms (*Tricholoma equestre*)
Peanut oil

Poisonous Insect/Reptile Bites

Snake bites
Spider bites
Massive bee stings
Fire ant bites

Cocaine-induced rhabdomyolysis is not uncommon. At least some degree of skeletal muscle injury and CPK elevation appears to be common in emergency department (ED) patients who present after using cocaine (11). The exact etiology is unclear but may be related to excessive energy demands placed on the muscle cell, cocaine-induced vasospasm with resultant muscle ischemia, direct toxicity to the cell membrane, seizure activity, or agitation associated with cocaine toxicity. In addition, adulterants used to "cut" cocaine may be myotoxic (11).

Phencyclidine hydrochloride (PCP) and amphetamine intoxication cause similar toxicity. In a retrospective series of 367 patients identified in a California ED with rhabdomyolysis, the majority had toxicological evidence of illicit drugs and alcohol, with 43% testing positive for methamphetamine (12). Only 11% of the patients in this series developed acute renal failure. Excessive physical activity appears to be associated with rhabdomyolysis related to PCP abuse. It is not clear if PCP is directly toxic to the myocyte (11). Amphetamines are not known to be directly myotoxic but, like cocaine, have vasoconstrictive properties that can cause myocytes to become ischemic. They additionally raise levels of norepinephrine and dopamine, which increase the adenosine 5′ triphosphate (ATP) demands of the cell membrane (11). Amphetamine-intoxicated individuals also often present as agitated, requiring physical and chemical restraint, which may contribute to the development of rhabdomyolysis. Hyperthermia and DIC may also be factors contributing to the development of rhabdomyolysis in these patients. Rhabdomyolysis associated with heroin injection has been linked to adulterants such as quinine. Opioids may also have direct cell toxicity, and heroin users tend to be stationary for prolonged periods of time, placing them at further risk to develop rhabdomyolysis (11).

In a series of 475 hospitalized patients with rhabdomyolysis, neuroleptic drugs led the list of prescribed drugs most commonly associated with rhabdomyolysis, followed by statin agents (3). The statins (3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors) are associated with mild CPK elevations, myalgia with and without elevated CPK levels, muscle weakness, muscle cramps,

myositis, and rhabdomyolysis. Myalgias can affect up to 10% of patients taking statins (4). The exact mechanism of muscle cell injury is unknown, but statins appear to reduce the production of small regulatory proteins that are important in maintaining the integrity of the myocyte. Clinically significant rhabdomyolysis with statins is uncommon, with an overall reported incidence of fatal rhabdomyolysis of 0.15 deaths per million prescriptions (13). The occurrence of renal failure with statin-induced rhabdomyolysis appears to be related to the magnitude of muscle injury, the patient's hydration status, and possibly other factors, such as concomitant medications or genetic predisposition. The risk of rhabdomyolysis appears to be dose-dependent, with the risk of myopathy increasing with higher serum concentrations of the statins.

Medications that inhibit the cytochrome P-450 3A4 system, such as the macrolide antibiotics, azole antifungals, and cyclosporine, increase the serum concentrations of selected statins and the risk of rhabdomyolysis. Other medications that increase the risk of statin-associated myopathy include the fibric acid derivatives (especially gemfibrozil), niacin, human immunodeficiency virus (HIV) protease inhibitors, verapamil, diltiazem, and amiodarone. Impaired renal or hepatic function, diabetes, hypothyroidism, heavy exercise, or surgery also appear to increase the risk of rhabdomyolysis in patients on statins (13).

Rhabdomyolysis due to strenuous or prolonged exercise can be seen in both untrained and trained athletes, especially if the exercise is conducted in extremely hot or humid conditions. Sickle-cell trait has been associated with exertional rhabdomyolysis; several fatalities have been reported (14). Survivors of high-voltage electrical injury or lightning strikes may develop rhabdomyolysis (7). Direct thermal cellular injury or electrical disruption of the sarcolemmal membrane is believed to be the etiology in these instances. Hyperpyrexic states can also outstrip cellular energy supplies, resulting in cell membrane dysfunction (15).

Infections (Table 213.4) may induce rhabdomyolysis by direct muscle injury or by inducing tissue hypoxia. Influenza is the most commonly reported viral etiology, followed by HIV infection and

enteroviral infection. Legionella species have been the most commonly reported bacterial organisms, followed by streptococcus species, *Francisella tularensis,* and *Salmonella* species (7). The myotoxic effects of *Legionella* are mediated through an endotoxin.

Hepatitis
Human immunodeficiency virus (HIV)
Varicella-Zoster
Rickettsial
Rocky Mountain spotted fever
Parasitic
Trichinosis
Other
Reye syndrome

Other toxins, such as carbon monoxide and mercuric chloride, are directly toxic to the muscle cell membrane. Snake envenomations and stings from Africanized bees and honeybees can cause rhabdomyolysis via direct myotoxins. The eating of quail fed with hemlock has been associated with outbreaks of rhabdomyolysis (15). Haff disease is a syndrome of unexpected rhabdomyolysis related to the consumption of certain types of fish. Recent US cases have been associated with buffalo fish (*Ictiobus cyprinellus*), a bottom-feeding species found mostly in the Mississippi River and its tributaries (16). Cases of rhabdomyolysis due to the ingestion of wild mushrooms (*Tricholoma equestre*) have been reported (17).

Certain genetic defects, such as McArdle syndrome (absence of muscle phosphorylase) or carnitine palmitoyltransferase deficiency, prevent the effective use of carbohydrates or lipids as energy substrates. These entities can cause recurrent episodes of reversible rhabdomyolysis (2). Finally, in immunologically mediated diseases (e.g., polymyositis and dermatomyositis), muscle cells may be injured by inflammation.

ED EVALUATION

Evaluation, as always, begins with confirmation of hemodynamic stability. The history should be directed at identifying any possible etiologic factors, including exposure to alcohol, cocaine, or other toxins. On physical examination, look for signs of focal or generalized muscular tenderness or swelling, and note any obvious trauma. Laboratory evaluation should include electrolytes, blood urea nitrogen (BUN), creatinine, glucose, CPK, calcium, magnesium, and phosphate. Serum albumin, uric acid, and coagulation studies may be helpful in some instances. False-positive elevations of cardiac troponin I have been reported in rhabdomyolysis (18).

CPK is the most sensitive test for rhabdomyolysis. Five times the upper limit of normal, in the absence of cardiac or brain injury, is often considered the threshold for the diagnosis. CPK is an excellent marker because it is present almost immediately following injury, is easily measured, and is not rapidly cleared. Elevations are seen 2 to 12 hours following muscle injury; levels peak in 1 to 3 days and

generally fall off within 3 to 5 days after muscle injury ceases (1). There is a linear correlation between CPK and creatinine levels (3). Investigations suggest a relationship between CPK level and the development of acute renal failure and mortality (3). Renal injury is uncommon with levels of CPK less than 15,000 to 20,000 U/L unless dehydration or sepsis is present (2).

Serum and urine myoglobin determinations have also been used to diagnose rhabdomyolysis. Myoglobin typically rises more quickly than CPK, so it may be helpful in the diagnosis of early rhabdomyolysis, but because its half-life in plasma is only 1 to 3 hours it can also be unreliable because it can completely disappear from plasma within 6 hours of injury (1). Urine tests that use guaiac, orthotolidine, or similar agents can detect myoglobin or hemoglobin in the urine but cannot distinguish between the two. False-negative tests for myoglobinuria can occur because of rapid clearance of myoglobin from the urine (2). In a recent series, urine myoglobin was detected in only 19% of the patients with rhabdomyolysis (3).

KEY TESTING

- Electrolytes
- BUN
- Creatinine
- Blood glucose
- Calcium
- CPK

ED MANAGEMENT

The goals of management are to treat the underlying cause or causes of rhabdomyolysis, to identify and treat complications, and to prevent acute renal failure.

Rhabdomyolysis may continue to proceed or may be exacerbated by excessive exertion, agitation, fighting of restraints, seizures, or abnormal posturing. These should be controlled by aggressive sedation with a benzodiazepine to prevent further muscle breakdown. Rarely, pharmacologic paralysis with nondepolarizing

neuromuscular agents and intubation may be required. Hyperthermia, if present, should also be aggressively treated.

Patients with hyperkalemia require continuous cardiac monitoring and aggressive intervention. Hypocalcemia is generally self-limited and rarely requires specific treatment unless the patient is symptomatic or has severe hyperkalemia (2); the same is true of hyperphosphatemia. As noted previously, the patient should be monitored for the development of compartment syndrome. Coagulopathy can generally be addressed by treating the underlying disease process.

The mainstay of treatment is early repletion of fluids (2). Reports suggest that patients with delayed fluid resuscitation are more likely to suffer renal injury (19). There are no prospective studies comparing aggressive and nonaggressive hydration for the prevention of renal failure in patients with rhabdomyolysis. Uncontrolled studies suggest the efficacy of early, aggressive isotonic fluid administration in preventing acute renal failure in crush-related or traumatic rhabdomyolysis (2,20). In the case of major crush events (e.g., building collapse or earthquake), aggressive fluid repletion should be initiated during extrication if possible and prior to evacuation (6). This treatment results in increased renal tubular flow rates, which facilitate the excretion of substances that may injure or obstruct the renal tubules. A target urine flow rate of 200 to 300 mL/hr has been suggested. The fluid of choice is controversial and there are no definitive studies in this regard. Most experts initially recommend isotonic saline (2). Some have suggested the use of lactated Ringer solution (21) or half-normal saline (15).

Many experts also recommend the use of intravenous sodium bicarbonate to alkalinize the urine, because myoglobin is toxic to the kidneys in acid urine and bicarbonate will reduce the risk of hyperkalemia. *There have not been any large, randomized, and controlled studies to date demonstrating the benefit of bicarbonate* (1,2). Comparative trials have either been retrospective (22) or have been confounded by the concurrent use of saline loading or a combination of alkalinization plus mannitol. Saline and sodium bicarbonate are a reasonable approach, particularly for patients with metabolic

acidosis. One source recommends checking the urine pH, and if less than 6.5, alternating liters of normal saline and 5% dextrose plus 100 mmol of bicarbonate (2).

The role of diuretics such as mannitol and furosemide is also unclear, with no study demonstrating clear benefit (1,2). They should only be considered following adequate fluid repletion. Mannitol (1 g/kg) should probably be considered if urine output is inadequate despite saline infusion, because it may convert oliguric renal failure to nonoliguric renal failure, which has a better prognosis. Mannitol increases renal blood flow and GFR, may reduce muscular swelling by acting as an osmotic agent, increases urinary flow, may prevent obstructive myoglobin casts by acting as an osmotic diuretic, and scavenges free radicals (15). Acute renal failure unresponsive to the aforementioned measures may require dialysis. Indications for dialysis include worsening renal failure, persistent hyperkalemia despite treatment, fluid overload and pulmonary edema, resistant metabolic acidosis, or persistent oliguria or anuria (2). The overall prognosis for ultimate recovery is good (1).

CRITICAL INTERVENTIONS

- Strongly consider rhabdomyolysis in the setting of seizures, unconsciousness, or agitation, particularly if associated with a history of drug use.
- Suspect rhabdomyolysis if the urine dipstick is strongly positive for blood with few or no red blood cells (RBCs) seen on microscopic examination of the urine; confirm the diagnosis by obtaining a CPK level.
- Aggressively hydrate with normal or half-normal crystalloid solution to maintain urine output at 200 to 300 mL/hr.
- Aggressively treat hyperkalemia.

DISPOSITION

Patients with rhabdomyolysis generally require admission to the hospital, as it is not possible to predict which individuals will develop complications. Patients with hyperkalemia, metabolic

acidosis, or evidence of renal failure, and those with other serious comorbid conditions, require hospital admission. Patients with hyperkalemia require admission to a monitored setting, and nephrology consultation is indicated if renal insufficiency develops or if metabolic abnormalities are unresponsive to usual medical treatment. Dialysis is required for some individuals. If renal consultation and dialysis are not available at the treating institution, transfer to a facility with those capabilities should be initiated.

Common Pitfalls

- Failure to consider rhabdomyolysis in patients with alcoholism or drug abuse, on rhabdomyolysis-associated medications, unconsciousness, prolonged immobilization, seizures, hyperthermia, or infection.
- Failure to pharmacologically control agitation, seizures, or abnormal posturing in patients who are at risk for rhabdomyolysis.
- Failure to evaluate for compartment syndrome.
- Failure to realize that the diagnosis of rhabdomyolysis cannot be ruled out on the basis of the serum or urine myoglobin alone.
- Failure to provide adequate hydration and to prevent or treat acidosis in patients with rhabdomyolysis.

PART 1 • GENERAL PRINCIPLES OF PEDIATRIC EMERGENCY CARE

CHAPTER 214

General Approach to the Pediatric Emergency Patient

Paul Ishimine

Children present frequently to the emergency department (ED) and pose special challenges to providers who are more accustomed to evaluating adult patients. They have different illnesses when compared to adults, and they have different responses to the same diseases. Communication with children can be challenging, and interaction with pediatric patients must involve parents or guardians as well.

Of the 130 million ED visits in 2010, 30 million visits or 23% of all ED visits were by children under the age of 18 years (1). One-quarter of all children under the age of 6 years visited EDs in 2011 (1). Generally, children tend to be less sick compared to adult patients. Children are triaged at lower acuities at the time of ED presentation and are more likely to be discharged home, as compared to adults (2). The two most common reasons for ED visits are cold symptoms and injury, the latter most commonly from falls (1).

While children are generally less ill than adult ED patients, EDs are the most common entry points into the health system for the vast majority of critically ill and injured children. The Institute of Medicine supports the idea of regionalization of pediatric emergency care so that critically ill and injured patients are directed to facilities with the capabilities of taking care of these children (3). This poses a challenge to emergency providers, since critical procedures in

children are infrequently performed in the ED (4). With regionalization, most emergency providers will have fewer opportunities to take care of seriously ill and injured children, and yet, all EDs and emergency providers must be able to assess and stabilize pediatric patients.

INITIAL ASSESSMENT OF THE PEDIATRIC PATIENT

The initial assessment of the pediatric patient can be based largely on observation (5). This clinical gestalt is formed, either consciously or subconsciously, by components of the Pediatric Assessment Triangle (PAT). The PAT is a useful tool to that uses only visual and auditory cues and allows the clinician to rapidly assess the severity of a child's condition. This general impression of the child's condition drives the urgency for treatment (5). The three components of the PAT include appearance, work of breathing, and circulation.

The appearance limb of the PAT is actually a mental status examination. It not only assesses brain function but helps to determine adequacy of circulation, ventilation, and oxygenation. Is the child irritable or lethargic? Does he or she respond to his or her environment in a way that is age-appropriate? Is she or he easily consoled when rocked or cuddled? Does she or he interact appropriately with her environment and caregiver? Is his or her look/gaze age-appropriate? Is the character of the cry weak, high-pitched, muffled, or atypical?

Work of breathing in infants and young children can best be assessed before touching the patient. Listen carefully for both inspiratory and expiratory sounds. Is there audible wheezing, stridor, or grunting? Are there intercostal, subcostal, or supraclavicular retractions? Is there nasal flaring or head bobbing? What is the preferred position of the patient?

Assessment of circulation to the skin can be determined by observing for pallor, cyanosis, or mottling. Frequently, the first objective indicator of compensated shock is a combination of tachycardia and pallor. The pale infant or young child should be considered in shock until proven otherwise. As circulation to the skin

becomes further compromised, patches of erythema or cyanosis interspersed with pallor (mottling) will appear.

Once the initial assessment is complete, a more formal assessment can then proceed, starting with measurement of the vital signs. Vital signs can be highly variable in the same patient and should be interpreted while considering the context in which these vitals were obtained. For example, an anxious child who is crying at triage is more likely to have tachycardia, tachypnea, and high blood pressure.

Normal heart rates for infants and children are age-dependent (Table 214.1) (6). In compensated shock, the first sign will usually be tachycardia. However, tachycardia is a very nonspecific finding and is also increased with pain, fear, and fever. The heart rate must be compared with pulse quality and mental status to determine the significance of either an abnormally fast or slow rate. The most common cause of a slow heart rate is respiratory compromise and hypoxemia. The quality of pulses is an important physical examination tool to monitor during stabilization and resuscitation. Central and peripheral pulse should be compared simultaneously.

TABLE 214.1
Normal Heart Rate and Respiratory Rate (6)

Age	Heart Rate, Beats/min, Median (Interquartile Range)	Respiratory Rate, Breaths/min, Median (Interquartile Range)
0–3 ms	143 (133–154)	43 (40–52)
12–18 mos	123 (112–132)	35 (32–42)
4–6 yrs	98 (89–108)	23 (21–25)
8–12 yrs	84 (75–93)	19 (18–21)
12–15 yrs	78 (69–87)	18 (16–19)

Blood pressure measurements are often difficult to obtain when infants and young children are agitated and crying. Furthermore, blood pressures defined as normal depend on the patient's age, sex, and height (Table 214.2) (7). Improper blood pressure cuff sizes, can cause incorrect readings. To obtain an accurate blood pressure, the cuff width should be at least two-thirds the length of the upper arm

of the child. Time should not be wasted during resuscitation and stabilization with attempts to obtain an accurate blood pressure. If the child is alert, crying, and responding to his or her environment, blood pressure measurements can wait until stabilizing interventions are under way. The lower limits for blood pressure (fifth percentile) are typically considered to be (8):

TABLE 214.2
Normal Blood Pressures by Age and Sex

	Boys		*Girls*	
Age (Years)	Systolic, mm Hg, Mean (Interquartile Range)	Diastolic, mm Hg, Mean (Interquartile Range)	Systolic, mm Hg, Mean (Interquartile Range)	Diastolic, mm Hg, Mean (Interquartile Range)
1	85 (83–87)	37 (46–38)	86 (85–88)	40 (39–41)
3	91 (89–93)	46 (45–47)	89 (88–91)	49 (48–50)
8	99 (97–100)	59 (58–60)	98 (96–99)	57 (56–58)
12	106 (104–108)	62 (61–63)	105 (104–107)	62 (61–63)
16	116 (114–118)	65 (64–66)	111 (110–112)	66 (65–66)

National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents. The fourth report on the diagnosis, evaluation, and treatment of high blood pressure in children and adolescents. *Pediatrics*. 2004;114:555–576.

- <60 mm Hg in term neonates (0 to 28 days)
- <70 mm Hg in infants (1 month to 12 months)
- <70 mm Hg $+$ (2 $\times$ age in years) in children 1 to 10 years
- <90 mm Hg in children ≤ 10 years of age

Capillary refill time is a cruder measurement of perfusion status and should generally be <2 to 3 seconds when an infant or child is in a neutral–thermal environment. Delays in capillary refill can occur if the ambient temperature is low (9). When an infant compensates for hypovolemia or hemorrhage, early skin signs include not only pallor and decreased peripheral pulses but cool distal skin temperature as well.

Respiratory rates are also age-dependent (Table 214.1) (6). Although rates above 60 breaths/min can periodically be normal for short periods of time in an infant, any rate above this, or any prolonged periods of tachypnea, must be considered abnormal until proven otherwise. Slow respiratory rates must alert the healthcare

provider to consider respiratory failure. The respiratory rate must always be interpreted in conjunction with heart rate and mental status when determining whether ventilatory efforts are adequate or insufficient.

Pulse oximetry is frequently utilized in the assessment of pediatric patients. Normal pulse oximetry values have not been established but are generally accepted to be 97% to 99%. This can vary throughout the day. The oxygen saturation is commonly lower during sleep, when it can be as low as 90% to 93% in normal patients (10). Nonetheless, pulse oximetry may be a useful screening tool in children with suspected respiratory pathology.

Temperature measurements should be obtained in children who present to the ED. Although body temperature can normally fluctuate, the generally accepted average core temperature is 37.0°C (98.6°F). Fever is generally accepted as a temperature of 38.0°C (100.4°F); conversely, hypothermia is commonly defined as a temperature below 35.0°C (95.0°F). Rectal temperature measurements provide the closest approximation to a core temperature measurement, and in young children, for whom a precise measurement of temperature leads to a specific plan of action (e.g., the initiation of an evaluation for sepsis in a young infant), this method is preferred over other, more convenient, means of temperature measurement.

An age-appropriate pain scale should be used to measure pain severity whenever significant pain is a complaint. Although the perception of pain is very subjective, intense pain should always be an issue of concern to the healthcare provider. Finally, a weight, measured in kilograms, should be obtained in pediatric patients. Medications are dosed in units per kilogram, and appropriate equipment size is often linked to patient weight. If an actual weight cannot be measured, weights should be estimated using a length-based measurement system.

AGE-SPECIFIC CONSIDERATIONS

A basic understanding of how developmental age affects child behavior is necessary to get the most out of the emergency

department assessment. Knowledge of language development and the sequence of physical and behavioral milestones can be quite helpful in determining the optimal approach to the assessment of an infant or young child. Table 214.3 summarizes age-related pediatric differences in language development, behavioral activities, and motor-physiologic milestones.

TABLE 214.3
Age-Specific Considerations

Age	Language	Behavioral	Motor/Physiologic
Birth	• Express needs and discomfort by crying	• No/limited eye contact • No social smile • No recognition of caretaker	• Acrocyanosis • Abdominal breathing • Irregular head control
2 mos	• Vowel sounds with pleasure • Babbles • Laughs aloud	• Social smile • Recognizes caretaker	• Tracks light • Grasps objects • Rolls over • Sits with support
6 mos	• Repetitive vowel sounds • Repetitive consonant sounds	• Stranger anxiety • Oral exploration • Imitative behavior • Independent activities	• Sits alone • Increasing mobility • Creeps • Crawls • Stands
12 mos	• Variable and progressive language capabilities • Jargon speech • Speaks in 2- to 3-word phrases	• Increasing curiosity • No fear of danger • Strong opinions • Egocentrism • Problem solve by trial and error	• Walks alone • Stiff running • Climbs stairs
2 yrs	• Comprehension greater than expression • Speaks in short sentences • Rapidly progressing language development	• Development of acceptable social patterns • Toilet training • Nightmares; fears of separation, bodily injury	• Refinement of both fine and gross motor skills
4 yrs	• Good verbal skills	• Cooperative during examination • Gain in independence • Ability to reason with adults • Fear of pain, procedures	• Specialized motor skills emerge (games)
Adolescence	• Expressive and comprehensive language skills mature	• Peer pressures replace parent control • Abstract thinking • Rational thought/analysis • Risk-taking	• Very mobile

Neonates (birth to 1 month) and young infants (1 to 3 months) have a limited behavioral repertoire. A neonate sleeps approximately 20 hours per day in early infancy. The young infant's expression of needs is by crying and is generally a sign of hunger or discomfort. Neonates typically lose weight during their first few days of life, but usually return to their birth weight by 10 to 14 days of age.

Older infants (3 to 12 months) begin appropriate interaction with their environment such as smiling with pleasure and recognition of

familiar faces. Babbling sounds emerge as the beginning of language development and motor activities begin to mature. When performing assessments on infants younger than 6 months of age, emphasis should be on the most important and least traumatic aspects of the examination first. Keeping hands and instruments warm and using distractions and a quiet soothing voice can assist in gaining cooperation and facilitating the examination process. The majority of the examination should be done in the caretaker's arms whenever possible. It is important to be aware of the increased risk of heat loss from a high surface-area-to-weight ratio. Providers should aim to maintain a neutral–thermal environment during the examination process.

Examination of 6-month to 1-year-old infants can be a challenge, especially if they have had previous negative experiences with healthcare providers. Always anticipate and expect separation anxiety and perform as much of the examination on the caregiver's lap as possible. It is often helpful to get at or below eye level of the infant during the examination. Toys and distracting sounds can be used to keep the infant from losing control. The *toe-to-head* approach to examining the infant should always concentrate on the least traumatic aspects of examination first. The ears and mouth should be examined last.

The toddler years (12 to 36 months) are manifested by increasing mobility and curiosity. Toddlers have little fear of danger, and the risk of preventable injury events increases dramatically as mobility progresses. When examining a toddler, obtain as much information as possible through observation, before laying on hands or a stethoscope. Magical games often help with difficult portions of an examination. For example, as the caretaker palpates the abdomen, he can "guess what the toddler had for breakfast earlier." Reassurance and praise goes a long way, and any painful procedure should be explained in very simple terms.

As preschoolers (3 to 5 years) young children begin to understand cause-and-effect relationships and learn to reason with adults. Their increasing independence outside the home becomes evident, but this newfound independence will often crumble during stressful

situations. It is not unusual for a 4-year-old to express plans for complete cooperation during a painful procedure, but when the procedure begins, she or he may lose control and become combative. Information given to a young child can often be misinterpreted and create unwarranted fear and anxiety.

School-aged children (5 to 12 years) have developed a stronger sense of cause-and-effect. It is important to speak directly to the child and obtain information from the child, supplementing that information by parental report. Praise and compliments go a long way. It is best to anticipate questions and address fears with simple and clear explanations during the examination. Always respect the patient's modesty. When there are options in performing a procedure, allow the child limited control. For example, one cannot negotiate the need for a blood draw, but they can negotiate whether the procedure is performed in the left arm or the right arm.

In many ways, adolescent (12 to 18 years) behavior is similar to that of the toddler; both are periods of rapid physical development and developmental changes. Adolescents are very mobile and risk taking and often have no fear of danger. They may not anticipate consequences, and may fail to use common sense before performing risk-taking activities. Peer pressure becomes very important. During a history and physical examination, adolescents should be separated from parents, and information should be obtained from the patient, not the caretaker. Privacy and confidentiality must be respected.

CONSENT AND CONFIDENTIALITY ISSUES

Most children who present to the ED for evaluation are accompanied by a parent or guardian, and usually the parent or guardian provides consent for the evaluation and management of these minors (i.e., persons under the age at which they can provide legal consent) and participates in the child's care. Indeed, the principles of patient- and family-centered care encourage collaboration between the patient, family, and provider (11). However, situations occasionally arise where a parent or guardian is unavailable to provide consent for treatment, when parental consent is unnecessary, or when parental refusal of consent is potentially dangerous.

For those minors who present to the ED unaccompanied by a parent or guardian, a medical screening examination and any life- or limb-saving interventions that cannot be safely delayed (including treatment of severe pain) should be undertaken while attempting to contact the parent or guardian, and should never be delayed because of difficulties obtaining consent. This is mandated by the Emergency Medical Treatment and Active Labor Act and falls under the doctrine of "implied consent." The legal basis for this is known as the "emergency exception rule" (12). If an emergency medical condition is not identified, then the emergency provider should generally seek consent before providing any additional, nonemergent care. The clinician should document attempts to contact the parent or guardian and the rationale for emergency interventions.

There are several situations where a minor, and not a parent or guardian, can consent to treatment. When a child is emancipated, he or she can consent to medical treatment. Criteria for emancipation vary from state to state, but most states recognize minors to be emancipated if they are married, on active duty in the military, or are self-sufficient and living independently. The "mature minor" exception allows a minor, generally over 14 years of age, with sufficient maturity and intelligence, to provide informed consent; the criteria for a "mature minor" also varies from state to state. Additionally, minors can usually consent to evaluation and treatment of certain conditions (e.g., pregnancy-related conditions, mental health issues, sexually transmitted diseases, substance abuse); these conditions also vary from state to state (1).

While a parent or guardian with adequate decision-making capacity may have the right to refuse treatment for his or her child, this authority is not absolute, and the appropriate child protective agency should be consulted if the parent or guardian makes a decision that places a child at significant risk or serious harm when compared to an alternative choice (12,13).

Adolescent patients should be afforded the opportunity to speak and be examined privately by emergency care providers, but they should be informed that the emergency provider may need to breach

this confidentiality if there is a potential danger to self or others or there needs to be a disclosure of abuse (11–13).

CHILDREN WITH SPECIAL HEALTHCARE NEEDS

While most children who present to the ED have a single-system, self-limited illness, some children have chronic medical conditions. Patients may have multiple medical problems, may be taking multiple medications, and may have indwelling medical devices. The involvement of the parents or caretakers of these children is even more imperative than with most children. Parents or caretakers usually can recognize when a child is at his or her baseline health status, and they frequently know why their child's condition has changed. Additionally, parents and caretakers are usually best able to assess the capabilities they have at home to take care of their children; thus, they should be involved in the disposition process. Early engagement of the patient's primary care physician and subspecialists can lead to a more directed evaluation in a child with a chronic medical condition. Both the American Academy of Pediatrics and the American College of Emergency Physicians have advocated the use of an Emergency Information Form, a concise summary of a patient's health status (14,15).

ED PREPARATION FOR CHILDREN

The majority of children seeking emergency care are seen in the EDs of general hospitals, so every ED needs to be prepared to assess and stabilize children. Despite the large numbers of children seen in general EDs, adherence to previously published guidelines for recommended pediatric supplies and equipment has previously been low (16,17).

Although most children can be discharged from the ED to which they initially present, EDs must be prepared to transfer these children to facilities that can provide definitive care, if needed. Guidelines for ED readiness call for the designation of physician and nurse coordinators for pediatric emergency care. Furthermore, these guidelines call for emergency physicians and nurses to have the skills, knowledge, and training to evaluate and treat children who

may be brought to the ED. Furthermore, EDs should have a pediatric patient care review process in place, as well as pediatric policies, procedures, and protocols that address specific pediatric topics, including pediatric-specific safety concerns, patient care, and interfacility transfers. Laboratory and radiology services should be appropriate for the ED services provided. Finally, guidelines endorsed by the American Academy of Pediatrics, American College of Emergency Physicians, and the Emergency Nurses Association make recommendations for the availability of pediatric equipment, supplies, and medications (18).

ACKNOWLEDGMENT

CHAPTER 215

General Approach to Neonates and Infants Less Than 12 Months of Age

Khoon-Yen Tay and Rakesh D. Mistry

While only approximately 3% of the almost 130 million emergency department (ED) visits in 2010 in the United States were for the care of infants less than 12 months of age, this age group offers a particular challenge to emergency medicine providers in all settings (1). For providers who rarely or infrequently care for children, evaluating infants creates significant discomfort and anxiety (2). Here we focus on age-specific differences in the evaluation of infants less than 12 months of age, separately addressing the neonate under 56 days and the infant from 8 weeks to 12 months of age.

The typical "past medical history" for most infants will be sparse, but must include the perinatal, birth, and vaccination history; information from this period may be invaluable in the continuing care of the infant. For example, in an infant presenting with bruising or signs of bleeding, the etiology could range from nonaccidental trauma (NAT), to failure of vitamin K administration in the immediate postnatal period.

In the first months of life, activity and well-being are best monitored by the infant's ability to perform very basic life activities such as feeding, urinating, stooling, and sleeping. Normal performance of even these most primitive functions may often exclude serious illness in young infants. Neonates, especially those who are breastfed exclusively, can lose up to 10% of their

birthweight in the first week of life. By 7 to 10 days of life, once maternal breast milk “let-down” has occurred and feeding regimens have become more regular, most neonates will have regained their birthweight and will gain an average of 20 to 30 g/d.

As infants grow, acquisition of gross motor skills, speech and vocalization skills, and general interaction with their environment become important markers of normal development and growth. The general timeline for developmental milestones in the first year of life is presented in Table 215.1. It should be noted that the range of development is wide, and achievement of milestones may differ from infant to infant.

TABLE 215.1
Examples of Major Developmental Milestones in Neonates and Infants 0–12 Months of Age

	1–2 months	3–4 months	5–6 months	7–8 months	9–10 months	11–12 months
Social and Emotional	Preferential social/responsive smile					
			Stranger anxiety			
			Feeds self			
				Indicates wants		
				Separation anxiety		
Language and Communication	Variation in crying					
	Quiets to voice					
			Turns head to sounds			
					Listens and responds to selective words	
					Uses symbolic jargon	
Fine Motor		Eyes follow 180°				
			Reaches for object			
			Palmar grasp			
			Thumb finger grasp			
				Bangs two objects together		
						Put block in cup
Gross Motor		Sits alone momentarily				
		Rolls back to stomach				
		Sits steadily				
					Stands alone	
				Pulls to standing		
						Walks alone

[a]Appearance and resolution of most developmental milestones occur within a range of ages, as depicted.

Measurement of vital signs, while as important as in older patients, takes on special significance in infants, potentially offering an early clue to occult disease; abnormalities such as fever or tachycardia may be the *only* indication of illness requiring immediate intervention. Evaluation of vital signs may be challenging, as

differences in normal age-appropriate vital signs are not intuitive to all providers. Not only are infant vital signs drastically different from those of adults, they also vary significantly from birth to 1 year of age, and specifically within the neonatal period. The normal ranges of vital signs, by age, are presented in Table 215.2.

TABLE 215.2
Vaccine Schedule for Pediatric Infants

Vaccines	Birth	1 month	2 months	4 months	6 months	9 months	12 months	15 months	18 months
Hepatitis B (HBV)	1st dose	2nd dose			3rd dose				
Rotavirus		1st dose	2nd dose						
Diptheria, tetanus, acellular pertussis (DTaP)		1st dose	2nd dose	3rd dose					
Haemophilus influenza type b (Hib)		1st dose	2nd dose	3rd dose					
Pneumococcal conjugate (PCV13)		1st dose	2nd dose	3rd dose					
Inactivated polio		1st dose	2nd dose	3rd dose					
Influenza					*Annual Vaccination*				
Measles, mumps, rubella (MMR)							1st dose		
Varicella							1st dose		
Hepatitis A							1st dose		

[a]Does not include premature infants or infants with chronic medical illnesses such as congenital heart disease.
Definition of hypotension based on American Heart Association Pediatric Advanced Life Support Guidelines, 2011.
Adapted from Nelson's Textbook of Pediatrics, 19th ed. 2011, and American Heart Association Pediatric Advanced Life Support Guidelines, 2011.

There are many unique aspects of the physical examination of infants. Anterior and posterior fontanelles, and palpable suture lines, are common throughout infancy and are occasionally mistaken for injuries. Primitive reflexes (suck, Moro, grasp) and clonus of the extremities are often the only findings of a normal neurologic examination. Among the more anxiety-provoking examination findings for emergency physicians (and parents) is crying. However, a preverbal infant cries for many reasons, including hunger, discomfort, need for attention; in cases where the infant cannot be consoled, etiologies such as pain and infection should be considered.

A high degree of suspicion for NAT must be maintained in this age group; presenting complaints are often vague, a history of trauma is absent, and external signs of injury are rare. The signs of abuse are often missed, explaining why over 40% of mortality from NAT is in infants less than 12 months of age (3). Injuries incompatible with developmental age accompanied by altered mental status (e.g., lethargy, listlessness, irritability, seizure) *without* a history of trauma

are red flags for possible NAT. Consultation with local child abuse experts must be sought for any child suspected of NAT (see Chapter 290).

GENERAL APPROACH TO THE NEONATE 0 TO 56 DAYS

History and Physical Examination

While the term "neonate" generally refers to patients from birth to 4 weeks of age, infants up to 8 weeks of age are included in this discussion. The history and physical examination must be tailored to assess a number of issues specific to neonates, including (1) the potential exposure to pathogens in utero or peripartum, placing them at risk for early sepsis, (2) an underdeveloped and unvaccinated immune system that is largely dependent on maternal antibodies, and (3) previously undiagnosed congenital anomalies or inborn errors of metabolism (IEM) presenting during this period.

Perinatal and birth history are vital elements of a thorough neonatal evaluation. Knowledge of prematurity or associated sequelae, such as respiratory distress syndrome, meconium aspiration, prolonged intubation, neonatal infections, repaired congenital heart defects, intraventricular hemorrhage, or necrotizing enterocolitis, can help focus evaluation of an acutely ill neonate.

Presence or absence of adequate prenatal care can be helpful: the majority of significant congenital diseases are diagnosed prenatally, including cardiac (e.g., hypoplastic left heart syndrome, transposition of the great arteries, tetralogy of Fallot, etc.), genetic (e.g., trisomy 21, 13, 18), neurologic (e.g., spinal dysraphisms), renal (e.g., renal agenesis, duplicate collecting systems), lung (e.g., lung hypoplasia from congenital diaphragmatic hernias, congenital cystic adenomatoid malformations), and bone (e.g., perinatal fractures often suggest osteogenesis imperfecta) anomalies. Additionally, routine prenatal care involves screening for pathogens potentially transferred from the mother to the fetus transplacentally during gestation or transvaginally at delivery. Herpes simplex virus (HSV), syphilis, cytomegalovirus (CMV), toxoplasmosis, and human immunodeficiency virus (HIV) may result in congenital infections or

major developmental complications postnatally. Perinatal treatment can moderate the risk of infection, such as administration of perinatal parenteral antibiotics for women with known group B streptococci colonization, and antiretroviral treatment for pregnant women with HIV. Absent or incomplete prenatal care in any neonate presenting to the ED should prompt a higher index of suspicion for specific perinatal infections and congenital anomalies. Additional birth history that may be of importance includes birthweight, administration of routine care such as vitamin K injection and erythromycin eye ointment, and results of newborn screening, all of which are routine received in the delivery room.

Social histories should document any prescription medications or illicit drugs that, may cross the placenta or be introduced into breast milk. Neonatal abstinence syndrome, may develop in infants exposed to addictive illegal or prescription drugs in utero, and then abruptly withdrawn at birth. These infants present with classic signs of withdrawal, such as irritability, poor feeding, jitteriness, seizure activity, diarrhea, diaphoresis, and excessive crying (4).

The review of systems for neonates stresses assessment of the five major activities common to this age group: feeding, urinating, stooling, sleeping, and breathing. Deviation from baseline in these activities may indicate distress or acute illness. Certain signs may be unique and should trigger increased concern, including the presence of fever, hypothermia, lethargy, increased fussiness, respiratory distress, intermittent cyanosis, or changes in skin color. Vomiting, diarrhea, rhinorrhea, and cough may be present from typical childhood viral illnesses; though other illnesses should be considered for each of these symptoms.

Neonatal hydration status is assessed by gaining a general sense of formula or breast milk intake and urine output; more specific questions about feeding, including quantity, volume, type of nourishment (breast milk vs. formula) are vital elements of the neonatal history. For neonates receiving formula reconstituted from a powder, it is important to ask caretakers how the formula is prepared. Overdilution of formula will result in an excess administration of free water to a renal system with reduced filtration

ability. This is in turn may lead to severe hyponatremia and refractory status epilepticus, which will only respond to interventions aimed at increasing the concentration of serum sodium such as 3% saline.

The poor sensitivity of the physical examination for detection of serious illness is among the most challenging aspects in the evaluation of infants less than 2 months of age. Multiple studies have shown that physicians are unable reproducibly assess which newborn infants are "well-appearing." The Yale Observation Scale (YOS) is a set of six observations that can be scored by medical providers for young febrile children, including observations such as the quality of the child's cry, color, and social response (5,6). However, in validation studies, the YOS alone was determined to be unreliable in neonates under 8 weeks of age and, conversely, a significant portion of infants with elevated scores had no objective evidence of serious illness (7). Consequently, more objective laboratory data are necessary in the evaluation of many neonates, particularly those presenting with fever. Nonetheless, a thorough head-to-toe physical examination remains of utmost importance, since detection of hallmark physical examination findings may provide useful clues for ED management. These include findings related to general appearance, tone, the anterior fontanel, and quality of cry.

Specific Disease Processes

Emergency providers should be aware of several disease processes exclusive to the newborn period. While many are common and benign, certain conditions are critical, often requiring prompt recognition, and immediate intervention to prevent morbidity and mortality. Thus, these processes should be considered in the general approach to an ill-appearing neonate in the ED; however, details regarding diagnostic workup and management can be found elsewhere in this textbook.

Neonatal sepsis refers to physiologic instability in the presence of an infecting pathogen, usually bacterial or viral, in an infant less than 8 weeks of age (56 days). In neonates, sepsis may originate, or produce meningitis, pneumonia, urinary tract infection (UTI), or

bacteremia (6,8–10). As discussed previously, neonates are at increased risk of invasive infection due to relatively poor host defenses and relatively compromised immune status. Presenting signs of sepsis in this age group are numerous, and include both fever ($\leq$38°C), and even more concerning, hypothermia ($<$36°C). Other presenting signs may include respiratory distress, tachypnea, tachycardia *or* bradycardia, and signs of poor perfusion such as mottling and prolonged capillary refill. Extreme fussiness or irritability, though neither sensitive nor specific, can herald a serious bacterial infection in a neonate, and should not be overlooked by emergency providers. As a result, infants less than 2 months of age are often empirically tested, and sometimes treated, for potential invasive bacterial infections. Further discussion on the workup and management of neonatal sepsis is discussed in Chapter 216.

Jaundice commonly occurs in neonates, and is usually benign in origin. Often, mild unconjugated hyperbilirubinemia is seen physiologically after birth, peaking within 48 to 96 hours of birth and lasting up to 2 weeks. "Breast milk jaundice," which presents around 4 to 7 days of life due to interactions of breast milk hormones with hepatic enzymes is typically self-limited and nonthreatening. "Breastfeeding jaundice," which occurs during the first few days of life before maternal breast milk let-down, results from dehydration, thus increasing the concentration of bilirubin in the serum, and occasionally requiring fluid supplementation. Although a frequent neonatal complaint, emergency providers must consider that (1) severely elevated levels of bilirubin in the blood can be toxic to the neonatal brain (kernicterus) and (2) the presence of conjugated hyperbilirubinemia implies an underlying pathologic process. Therefore, a careful approach to the jaundiced infant is required. In specific cases, when jaundice is present in the entire body, and associated with lethargy, poor feeding, and reduced urine output, evaluation for kernicterus, hepatic dysfunction, sepsis, and ABO incompatibility is necessary. Prompt institution of phototherapy, hydration, or even transfer to a tertiary-care facility may be necessary (11).

Inborn errors of metabolism (IEM), encompasses a group of disorders that result from disruption of the normal enzymatic function within mitochondrial cycles and cascades. The consequence is buildup of toxic precursors and metabolites, or the inability to produce vital proteins and molecules necessary for cellular function. As a result, these disorders often present after the onset of enteral feeding, and largely are diagnosed in the newborn period. Presenting signs of an IEM include poor feeding, vomiting, hypoglycemia, seizures, and lethargy. Histories of sudden decompensation after a prolonged period of fasting, or after initiation of common infant formulas, are helpful clues of a possible IEM diagnosis. Currently, the majority of IEMs are detected via newborn screening, prior to onset of symptoms; perinatal diagnosis allows for institution of specific formula to compensate for metabolic dysfunction. However, providers should not be falsely reassured by a reported normal newborn screen, as these screening tests vary by individual state and local, and are not always comprehensive. In some cases, physical examination findings, such as ambiguous genitalia in the case of congenital adrenal hyperplasia, can also lead to early diagnoses of IEM. Discussion about the diagnosis and treatment of pediatric inborn errors of metabolism is found in Chapter 275.

Congenital heart diseases are among the most feared diagnoses when ED physicians are faced with an in ill neonate. Fortunately, owing to the advent of fetal echocardiography, the majority of *significant* congenital heart lesions are identified in utero, and adverse events are avoided as pediatric cardiac intensivists and neonatologists are able to intervene immediately after birth. Nonetheless, congenital heart defects may elude prenatal or perinatal diagnosis, such as in cases of poor prenatal care or home birth; these situations should alert the emergency provider to the possibility of newly diagnosed congenital heart disease. Congenital heart anomalies, which rely on a patent ductus arteriosus (PDA) to maintain either systemic or pulmonary circulation, so-called “ductal-dependent lesions,” will often present in the first few days of life, as the ductus arteriosus is closing, leading to severely reduced cardiac output. Consequently, these neonates often present with a sepsis or

shock-like picture, with evidence of poor perfusion, decreased mental status, poor or labored feeding, and worsening respiratory distress. Severe hypoxia is usually present and unresponsive to administration of supplemental 100% oxygen. Examples of lesions that rely on a PDA to supply the systemic circulation include hypoplastic left heart syndrome, critical aortic stenosis, and critical coarctation of the aorta; congenital heart disorders that rely on a PDA for maintenance of pulmonary circulation include pulmonary atresia, critical pulmonary stenosis, tricuspid atresia, and tetralogy of Fallot. More subtle presentations of congenital heart disease are possible and subtle signs such as diaphoresis with feeding, irritability, or poor weight gain may manifest, as well as physical findings such as hepatomegaly or intermittent cyanosis. In any infant in whom a diagnosis of congenital heart disease is considered, the physical examination should concentrate on obtaining vital signs (specifically blood pressure and oxygen saturation) in all four extremities (or at the very least, the right upper extremity and a lower extremity), perfusion status, cardiovascular examination (including pulses in the upper and lower extremities), a lung examination, and examination for hepatomegaly. Further discussion on the use of other diagnostic testing and interventions are discussed in Chapter 268.

Abdominal pathology is not common among neonates; however, two notable conditions are unique to infants in the first 2 months of life. Hypertrophic pyloric stenosis is typically a more benign diagnosis in an infant 3 to 6 weeks of age, presenting with nonbilious projectile emesis immediately after feeding. Hypertrophy of the pylorus effectively produces an obstruction, preventing movement of gastric contents to the duodenum, and subsequently large volume, forceful emesis. Patients may require fluid resuscitation if diagnosis is delayed, but surgical correction (pyloromyotomy) is usually performed on an urgent, not emergent, basis. Malrotation with midgut volvulus, on the other hand, is a true abdominal catastrophe, resulting from abnormal rotation of the bowel in utero resulting in an unfixed segment of bowel that can twist, strangulating itself from its blood supply, resulting in bowel ischemia, necrosis, and death. Neonates with bilious emesis have malrotation with midgut volvulus

until proven otherwise. Other common presenting signs are poor feeding, lethargy, and shock. Resuscitation in the ED and immediate surgical consultation is indicated, prior to emergent surgical correction (laparotomy with a Ladd procedure). Discussion on the diagnostic workup and management of these two diagnoses are discussed in Chapters 271 and 272.

GENERAL APPROACH TO INFANTS 2 TO 12 MONTHS OF AGE

History and Physical Examination

The approach to infants between 2 and 12 months of age presenting to an ED differs from that of infants less than 8 weeks of age for several reasons. At 2 months of age, infant immune systems are more robust and most infants have received their first set of vaccinations. Routine vaccination in the first year of life confers protection from the following pathogens: *Corynebacterium diptheriae, Clostridium tetani, Bordatella pertussis, Haemophilus influenza* type B*, Streptococcus pneumoniae,* poliovirus*,* rotavirus, and hepatitis B virus. Infants receive these vaccines in a series at 2, 4, and 6 months of age; evidence has shown that significant immunity is conferred after the first set of vaccines has been administered at 2 months (Table 215.3) (12). Additionally, with continued growth and development, infants interact more with their environment, making assessment easier. More importantly, the physical examination becomes increasingly reliable and more specific allowing practitioners to more frequently and accurately ascertain general appearance and detect disease in specific organ systems (13,14).

TABLE 215.3
Vaccination Schedule for Children from Birth to 18 Months of Age

Vaccines	Birth	1 month	2 months	4 months	6 months	9 months	12 months	15 months
Hepatitis B (HBV)	1st dose	2nd dose			3rd dose			
Rotavirus		1st dose	2nd dose					
Diptheria, tetanus, acellular pertussis (DTaP)		1st dose	2nd dose	3rd dose				
Haemophilus influenza type b (Hib)		1st dose	2nd dose	3rd dose				
Pneumococcal conjugate (PCV13)		1st dose	2nd dose	3rd dose				
Inactivated polio		1st dose	2nd dose	3rd dose				
Influenza					*Annual Vaccination*			
Measles, mumps, rubella (MMR)							1st dose	
Varicella							1st dose	
Hepatitis A							1st dose	

[a]Adapted from Advisory Committee on Immunization Practices (ACIP) Recommended Immunization Schedule for Persons Aged 0 Through 18 Years—United States, 2013. MMWR, February 1, 2013; 62(01):2–8.

While birth history and past medical history remain important, other historical information is also valuable. Determination of vaccine status will give providers a higher index of suspicion for vaccine-preventable infections if a patient is un- or undervaccinated. The history of present illness in this age range will be of greatest yield in determining the etiology of the infant's presenting complaint. Length and severity of symptoms and a general assessment of the infant's activity, oral intake, and output remain important. Knowledge of ill contacts and exposure to other young children in daycare is helpful as the majority of illnesses in this age group are viruses that are highly contagious. Physical examination findings in this age range are more reliable, including the level of alertness, general tone, and presence of true irritability and meningismus. With respect to specific examination findings, the posterior fontanelle closes during this time period, though the anterior fontanelle remains open until after one year of age, allowing for some protection from increased intracranial pressure. A general sense of whether the infant is functioning appropriately for developmental age is also important. While it is not imperative to remember the specific age range for each developmental milestone (Table 215.1), it is helpful to remember that motor and neurologic development occurs in a cranial to caudal fashion, and has several major milestones, such as when infants are capable of rolling over on their own (~4 to 5 months), then when they can sit up unassisted (~6 months), followed by crawling and cruising (pulling to stand and walking while holding on to solid objects) (~9 months), and finally walking (~12 months). Histories deviating from normal

developmental milestones are important clues in the assessment of injuries potentially attributable to NAT.

A number of chief complaints are common in this age group. More comprehensive descriptions of these disease processes, including diagnostic evaluation and management, are available in other chapters.

Fever is one of the most common ED complaints for infants 2 to 12 months of age (15). In contrast to neonates, the occurrence of occult sepsis in an otherwise well-appearing immunized infant presenting with fever is very uncommon. The overwhelming majority of well-appearing infants with fever have a viral illness. Therefore, historical information should focus on associated symptoms to help direct the diagnostic evaluation should additional testing be required. Even for unusual presentations of fever with nonspecific blanching maculopapular exanthems, physicians can often be assured that these are "viral exanthems" from common viral infections in the setting of a well-appearing infant. Usually with these presentations, no further workup or evaluation is necessary, and owing to vaccination programs, the incidence of occult infections, specifically bacteremia, has diminished to the point where laboratory testing with CBC and blood cultures is *rarely* indicated (16,17). (Refer to Chapter 222.)

Contrary to the incidence of occult blood-borne infection, the incidence of occult UTI, in the setting of specific risk factors, remains appreciable (18,19). In female infants up to 12 months of age, uncircumcised male infants up to 12 months of age, and circumcised male infants up to 6 months of age, presence of a high fever $\leq$2 days without any other symptoms is concerning for presence of a UTI and obtaining a sterile specimen of urine for urinalysis and culture is recommended (20). Diagnostic evaluation and management of UTIs in children is covered in detail in Chapter 288.

Respiratory complaints are extremely common among infants presenting to EDs especially during the winter months. Bronchiolitis is a respiratory viral illness unique to young infants. Patients with bronchiolitis have signs and symptoms of both upper and lower respiratory tract infection: rhinorrhea and congestion with tachypnea, retractions, and scattered wheezes, rhonchi, or crackles

on lung examination. Hypoxia may or may not be present, depending on the severity of the illness. The most significant issue in infants with bronchiolitis is dehydration. Insensible losses are greatly increased in infants with tachypnea, as a small amount of water vapor is exhaled with each breath. This is compounded by increased difficulty feeding, making dehydration and hypoglycemia additional issues guiding treatment. Infants by and large tolerate tachypnea well over long periods of time and do not “fatigue” in the same manner as adult patients.

Croup, or layrngotracheobronchitis, is common in older infants, and typically results from infection of the vocal cords by parainfluenza viruses. Children with croup will often have a history of an antecedent upper respiratory infection that acutely worsens (often in the nighttime) with development of a barky, seal-like cough and inspiratory stridor. Severity of illness is determined by presence of respiratory distress, increased work of breathing, and hypoxia. Croup is often contrasted with epiglottitis, a bacterial infection with high complication rate; however, it should be noted that epiglottitis is extremely rare in the post-HiB vaccination era.

Foreign body aspiration should be considered in infants who are developmentally able to grasp and place objects in their mouths, as well as infants with toddler-age siblings. A history of a choking episode and focal lung examination findings may or may not be present, so a high index of suspicion should be maintained in infants with respiratory distress and no clear infectious etiology. Diagnostic evaluation and management for bronchiolitis, croup, pneumonia, and foreign body aspiration is covered in Chapters 261, 264, and 265, respectively.

Vomiting, with and without diarrhea, is another common complaint presenting in the infant less than 1 year of age. While presentations of malrotation with midgut volvulus are still possible after 2 months of age, it is less common. Gastrointestinal complaints such as nonbilious vomiting, particularly when accompanied by nonbloody diarrhea, are highly indicative of viral gastroenteritis in infants less than 1 year of age. Prior to the addition of the rotavirus vaccine to routine infant immunization schedules in 2006, rotavirus

was a frequent cause of viral gastroenteritis. While the morbidity from viral gastroenteritis has declined significantly since 2006, other gastrointestinal viruses, such as norovirus, continue to produce significant disease (21). In cases of acute gastroenteritis, assessment of the infant's hydration status is paramount. Assessment of dehydration includes obtaining pertinent history of oral intake, urine output, and frequency and volume of the emesis and diarrhea. Special attention on physical examination should be paid to the patient's level of alertness, perfusion and skin turgor, mucous membranes, and evidence of sunken eyes or anterior fontanelle. With respect to vital signs, infants primarily compensate hemodynamically via increasing their heart rate. Therefore, tachycardia is the first sign of dehydration, and will be present well before hypotension in infants who are severely dehydrated. Fortunately, validated measures of dehydration exist, to assist clinicians in assessment and institution of interventions, such as oral rehydration therapy (22–25). Diagnostic evaluation and management of viral gastroenteritis is covered in Chapters 223, 224, and 225.

Parents frequently present their infants for care in the ED with a suspicion of pain localized to the abdomen. Abdominal pain and complaints are largely limited to benign conditions such as acute gastroenteritis and constipation; however clinical suspicion for certain pathologies should be maintained. While intermittent crying episodes, accompanied by a history of drawing his or her knees up to the chest, are often a sign of constipation, even in the setting of history of hard or infrequent stools, and a normal abdominal examination does not preclude consideration of intussusception. An abdominal emergency unique to the older infant and toddler, intussusception is the result of telescoping of one piece of bowel into another, most often the ileum into the cecum. This is followed by mucosal edema, venous congestion, and obstruction which is maniested by severe, intermittent pain. A history of acute, intermittent, severe abdominal pain, bloody stools, and vomiting which spontaneously resolves and that alternates with normal activity is classic. Depending on the time of examination relative to a painful episode, the abdominal examination can range from normal

(soft and nontender) to distended and tympanitic with a tender mass felt in the right lower quadrant (Dance sign). While the classic finding of current jelly stools is a hallmark, the presence of occult blood in the stool should raise the suspicion of intussusception in the setting of possible symptoms. Younger children with intussusception may also present with intermittent altered mental status without any of the classic symptoms described above, and the diagnosis should be considered in young children with lethargy, hypotonia, and altered consciousness. The diagnostic evaluation and management of intussusception is covered in Chapter 270. The highly variable presentation of intussusception truly highlights the challenges of the diagnostic approach to infants under a year of age, and emphasizes the importance of a careful history and examination.

CONCLUSION

It is imperative for emergency physicians to approach infants under 12 months of age more judiciously than older children, and to note the issues and specific pathologies typical of neonates less than 2 months, and infants between 2 and 12 months. Normal changes that occur with growth, such as developing immune systems, continuous exposure to new pathogens, and neurodevelopmental advancement, in addition to the limitations in accurately reporting pain and distress, pose unique challenges to caring for neonates and infants. Adding to the complexity, reassuring physical examination findings in neonates can be misleading and providers should maintain a high index of suspicion for infectious pathologies, as well as abnormalities of the cardiac, abdominal, and metabolic systems in their ED assessments. Physical examination findings (or lack of pertinent physical examination findings) can be used to more reliably assess the older infant; therefore, a history of present illness with a targeted physical examination should allow an ED provider to diagnose the vast majority of illnesses. Familiarity with the general approach to this patient population, as well as knowledge of the disease processes discussed in this textbook, will permit emergency physicians to perform a stepwise, careful, and comprehensive assessment, and

more accurately initiate important evaluation and management strategies.

PART 2 • GENERAL PRINCIPLES OF RESUSCITATION, PROCEDURAL SEDATION, AND PAIN MANAGEMENT

CHAPTER 216 Newborn Resuscitation

Rodney B. Boychuk

Birth produces major physiologic changes in the newborn, the most important of which concern breathing. It is not surprising, therefore, that approximately 10% of all newborns require some type of resuscitation immediately following birth to establish spontaneous respirations (1–3). The majority respond to simple maneuvers such as drying, suctioning, administration of supplemental oxygen (room air is 21% oxygen), and stimulation ("SOS"). For some, however, more invasive resuscitation efforts may be required. At every delivery, there should be at least one person whose primary responsibility is the newborn and who is capable of performing a complete resuscitation, including tracheal intubation and medication administration.

PATHOPHYSIOLOGY AND PRINCIPLES OF RESUSCITATION

The goal of newborn resuscitation is to facilitate the transition from fetal (intrauterine) to newborn (extrauterine) life. These recommendations are also applicable to neonates who require resuscitation in the first weeks of life beyond delivery. Prior to delivery, the fetal lungs are fluid-filled, with high pulmonary arterial pressure and little pulmonary blood flow. Coexisting with this is fetal systemic hypotension, resulting in preferential high placental flow. Normal fetal blood flow is dependent upon intra- and extracardiac shunts (foramen ovale and ductus arteriosus) whereby blood largely bypasses the lungs and the left side of the heart, and goes to the placenta for gas exchange. After the umbilical cord is clamped

establishment of adequate spontaneous ventilation, or assisted ventilation if needed, is essential for extrauterine survival.

During the first initial respirations, displacement of fetal lung fluid as the alveoli expand and the establishment of functional residual capacity are necessary for a smooth transition. In addition, the introduction of oxygenated gas (room air) into the lung causes pulmonary vascular resistance to decrease. Clamping of the umbilical cord leads to increased systemic vascular resistance, resulting in closure of the foramen ovale and ductus arteriosus and an increase in pulmonary blood flow and the establishment of normal extrauterine circulation (4). This normally smooth transition can be interrupted in the antepartum, intrapartum, or postpartum stages. It is not possible to predict every case of asphyxiation in the newborn; however, certain prenatal factors should alert the emergency physician to the possibility (Table 216.1).

TABLE 216.1
Significant Maternal History

1. Prematurity: many require ventilatory support and possibly surfactant
2. Multiple gestations: multiple resuscitation setups; more personnel required
3. Meconium: suction at perineum/trachea (if nonvigorous) before stimulation.
4. Maternal drug (opiate) abuse: Avoid naloxone; it may precipitate seizures
5. "Maternal" bleeding: may require colloid or O-negative blood resuscitation
6. Maternal fever or prolonged rupture of the membranes

The type of resuscitation necessary depends on when resuscitation is started relative to the onset of asphyxia. Deprivation of ventilation and, therefore, oxygen leads to progressive bradycardia, decreased neuromuscular tone, and finally, primary apnea (5). Room air oxygen, and stimulation induce spontaneous respirations in most newborns at this stage, resulting in an increase in heart rate (HR) to over 100 beats/min. However, if asphyxia continues, irregular, ineffective gasping occurs, with bradycardia and flaccidity, until the newborn takes his or her last gasp and enters into the phase called secondary apnea. Once secondary apnea occurs, death is imminent unless resuscitation with assisted ventilation and oxygen is initiated.

From a practical standpoint, it is difficult to distinguish primary apnea from secondary apnea; therefore, all apneic newborns should be assumed to be in secondary apnea and treated with ventilatory assistance. Unlike adults requiring resuscitation, bradycardia is a secondary manifestation of hypoxemia, and must be treated with ventilation and oxygen.

The most important initial action is to ventilate and expand the partially collapsed, fluid-filled alveoli. This results in expansion of the lungs and clearance of alveolar fluid. Oxygen is a very potent chemical stimulator of the respiratory center in the brain and decreases pulmonary vascular resistance, resulting in increased pulmonary blood flow and improved gas exchange. Once oxygenated blood reaches the bradycardic hypoxic myocardium, HR, myocardial contractility, cardiac output, and tissue perfusion increase.

Too much oxygen, however, can cause oxygen toxicity including lung injury and retinopathy of prematurity (6). In most cases, room air is adequate for successful resuscitation (7,8); within 10 minutes of birth, oxygen saturations of 80% and greater are achieved (9), in healthy preterm and term infants without supplemental oxygen.

The 2010 American Heart Association (AHA/)American Academy of pediatrics (AAP) International Liaison Committee on Resuscitation (ILCOR) (1,3,8) has recommended the use of 100% oxygen if the HR is below 60 after 90 seconds of resuscitation. Further use of supplemental oxygen should be based on pulse oximetry monitoring. The oxygen saturation may remain in the 70% to 80% range for several minutes following birth. Current targeted SpO_2 levels for term infants based on the time after delivery are defined in Table 216.2 Most institutions have modified their previous resuscitation protocols and now utilize no supplemental oxygen for initial resuscitation and use 30% oxygen only for bradycardic newborns of less than 30 weeks' gestation (8). However, hypoxia must be avoided; if lower concentrations of oxygen are utilized during resuscitation but there is no appreciable improvement in the infant's HR or respiratory effort, additional supplemental oxygen must be added.

TABLE 216.2
Targeted Preductal SpO_2 After Birth (Right Arm)

1 min : 60–65%
2 min: 65–70%
3 min: 70–75%
4 min: 75–80%
5 min: 80–85%
10 min: 85–95%

Distention of the alveoli stimulates stretch and other pulmonary receptors, which results in stimulation of the respiratory center to increase ventilation (Hering–Breuer reflex). Thus, ventilation alone, with distention of the alveoli, has a beneficial effect.

To summarize, resuscitation of the asphyxiated newborn should primarily include ventilation for treatment of respiratory depression or gasping, with room air (or oxygen if needed to correct hypoxia).

Newborns may not respond to standard resuscitation measures for a variety of reasons. A key step is recognizing when a newborn is **not** responding to resuscitative efforts. If this occurs, the causes of resuscitation failure or deterioration must be sought and corrective action begun immediately (Table 216.3).

TABLE 216.3
Special Situations Resulting in Nonresponse to Resuscitation

Technical Problems

- Inadequate airway: positioning/ventilation
- Inadequate mask to face seal
- Inadequate pressure
  - Inadequate oxygen
  - Equipment failure
- Obstruction (mucus/meconium)
- ETT in esophagus
- ETT down too far

Unrecognized Pulmonary Problems

- Pneumothorax
- Diaphragmatic hernia
- Intrauterine pneumonia/sepsis
- Hypoplastic lungs
- Pleural effusion(s)/Hydrops Fetalis

Severe Metabolic Problems

- Hypothermia
- Hypoglycemia
- Acidosis

Other Problems

- Extreme prematurity
- Central nervous system
  - Injury
  - Narcosis
- Congenital anomalies
  - Upper airway
  - Lower airway
  - Pulmonary
- Cardiac structural/congenital heart block
- Neurologic sign
- Severe anemia, hypovolemia

Hypothermia and hypoglycemia are common occurrences in newborns requiring resuscitation and must be treated if present. Cooling results in increased oxygen consumption, increased metabolic rate and utilization of glucose and glycogen, increased lactic acid production, and increased acidosis (both respiratory and metabolic); therefore, the newborn must be kept warm (10). It is also important to prevent *hyper*thermia (11).

Practical Aspects of Resuscitation

Every emergency department (ED) delivery should be considered an emergency until proven otherwise. Once notified, the ED resuscitation team sets in motion the following: (1) preparation, (2) assessment, and (3) management. Preparation must occur well in advance of the delivery. The resuscitation of a depressed and asphyxiated newborn requires at least two people, and ideally three: a trained physician, nurse, and respiratory therapist make an ideal team to perform the two basic principles of resuscitation: (1) SOS (suction, oxygen, and stimulation) and (2) do not hesitate to ventilate, (i.e., if not breathing, start positive pressure ventilation [PPV]) (Fig. 216.1).

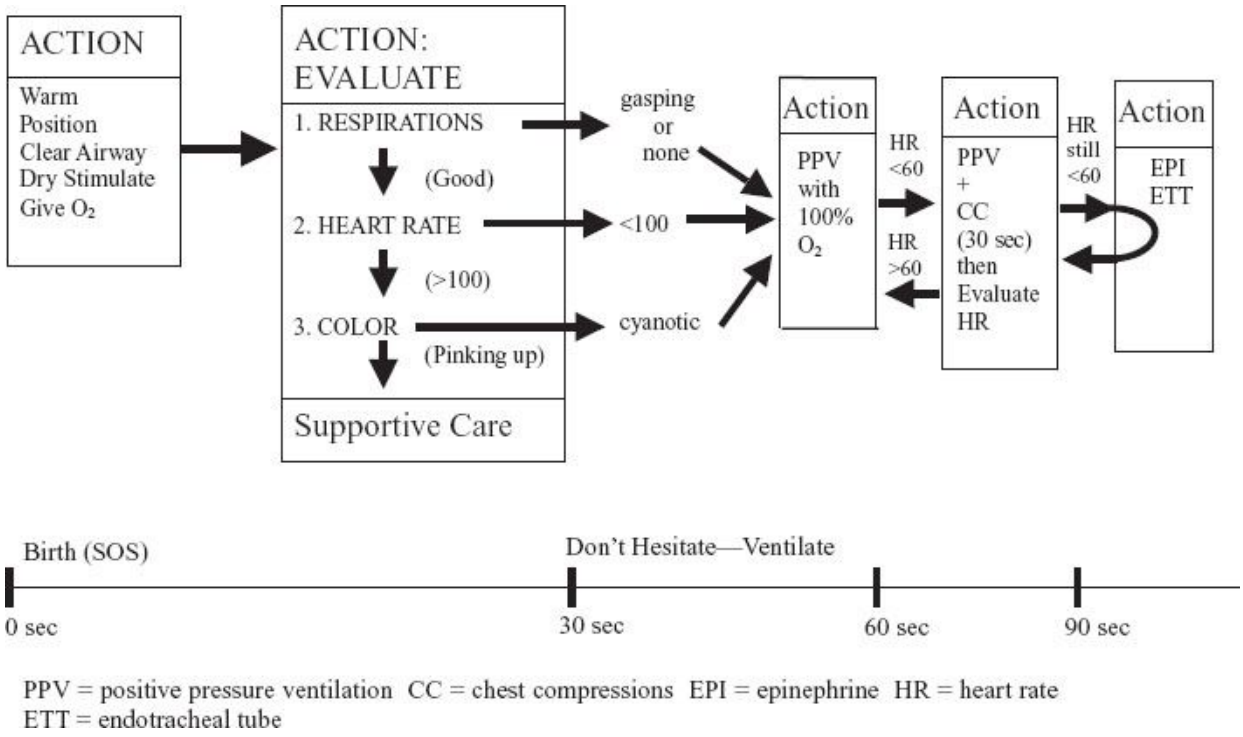

FIGURE 216.1 Neonatal Resuscitation algorithm (excluding nonvigorous meconium birth): Action versus time (seconds).

Table 216.4 outlines equipment that should be maintained and readily accessible at all times. It is advisable that all EDs be equipped with newborn resuscitation tray that includes emergency resuscitation equipment and algorithm charts specific for various

gestational ages or weights. It is essential that all ED personnel familiarize themselves with the resuscitation tray, and that daily checks be made to ensure presence and proper function of all the equipment. In addition, a radiant warmer should be kept on the unit; personnel skilled in newborn resuscitation must be immediately available (5).

TABLE 216.4
Practical Aspects of Resuscitation: Preparation of Equipment

1. Overhead radiant warmer: on and working. Warm blankets, caps.
2. Suction: on and working; catheters (sizes 8 F, 12 F, 14 F) immediately available;(1) blue bulb suction open and ready,(2) meconium aspiration device immediately available.
3. Oxygen supply: on and working. Blender ideal.
4. Laryngoscope and number 0 and 1 straight blades: batteries fresh, bulb secure, light a bright "white" intensity when turned on.
5. Endotracheal intubation tubes: sizes 2–4 mm ready.
6. Pressure-monitored anesthesia bagging apparatus: setup tested and ready. Face masks in premature and newborn sizes. Resuscitation bags: 250 mL for premature, 450 mL for term infant.
7. Nurse: ready to start the timer and monitor the infant's HR.
8. Physician: ready to evaluate, suction, laryngoscope, ventilate, intubate, and carry out further procedures.
9. Respiratory therapist: ready to administer oxygen, suction, and assist with ventilation and intubation.
10. Other equipment: meconium aspirators, umbilical catheters (3.5 F and 5 F), syringes, three-way stopcock, catheterization trays, chest tube trays, and drugs—epinephrine, volume expanders, naloxone, glucose, saline flush—immediately available or drawn up.

ASSESSMENT OF THE NEWBORN

Assessment is the physician's responsibility. If a physician is not available, the most skilled nurse or respiratory therapist must perform this role. From the instant of birth until resuscitation is complete, this individual evaluates the infant repeatedly, assessing the degree of asphyxia and the newborn's response to resuscitation. Even before the cord is clamped, evaluation of the respiratory effort and cry, HR, and color should be started. The term "integrated findings" (compound and ongoing action of all signs) is utilized, with

all signs being evaluated simultaneously as a group (2). The compromised newborn may exhibit any or all of the following: (1) depressed respiratory drive/gasping or apnea, (2) bradycardia; (3) poor muscle tone, (4), cyanosis and/or (5) low blood pressure.

The Apgar score per se plays no roll in determining the need for resuscitation. The components of the score, however, are important; HR being the single most important factor to monitor. Respiratory effort, color and muscle tone serve as guides to help guide further resuscitative efforts.

INITIAL RESUSCITATION OF THE NEWBORN

Figure 216.1 neonatal resuscitation algorithm describes actions that should be taken based on the time from birth. Broadly, the initial steps in a newborn resuscitation are: position under a warmer, clear the airway (including tracheal meconium suctioning if necessary); suction the mouth and nose (in that order); dry; remove wet linen; and reposition. During this time, simultaneously evaluate the newborn's respiratory effort and HR (2). Once placed under a radiant warmer, the newborn is positioned supine, or lying on the side with the head in a neutral or slightly extended position. This will facilitate optimal opening of the airway. Suctioning of the mouth, and then the nose, can be accomplished with a bulb syringe or mechanical suction device. Do not suction for a prolonged period, too deeply or too vigorously. In addition, do not pass the suction catheter into the stomach as vagally mediated apnea and bradycardia may occur (10). Unless meconium is present, the newborn should be thoroughly dried with warm blankets to prevent heat loss and stimulate spontaneous respirations. Wet blankets should be removed immediately. Reposition the infant as needed, and give oxygen as necessary. Stimulation is provided by rubbing the back or flicking the soles of the feet. Following this process again, simultaneously and continuously reevaluate HR and respiratory effort. Spontaneous respiratory effort is adequate if the newborn is able to maintain a HR higher than 100 beats/min and is breathing well or crying.

Newborns who remain apneic throughout the initial steps or who have gasping respirations require PPV with a bag valve mask (BVM)

device. It is important NOT to delay PPV by prolonging free flow oxygen and stimulation. If the newborn remains apneic provide PPV **(do not hesitate to ventilate).** Ventilate for about 30 seconds, then reassess. HR can be assessed by palpating the base of the umbilical cord; if a pulse is not palpable, auscultate the central left chest with a stethoscope. In the well newborn, the HR should remain greater than 100 beats/min. A HR less than 100 needs to be closely monitored and PPV initiated (or continued). If the HR remains less than 60, for greater than 30 seconds, further intervention with oxygen, chest compressions, appropriate diagnostic evaluation, and, infrequently, medications is indicated. Ideally, with a team present, the complex of signs can be evaluated simultaneously, with each individual monitoring a specific one.

A healthy newborn will eventually become and remain pink without supplemental oxygen. Acrocyanosis, or peripheral cyanosis, is not an unusual finding at birth. It is thought to occur secondary to cold stress and initially sluggish circulation; not because of hypoxemia (9). True cyanosis, or central cyanosis, is determined by examining central structures, particularly the oral mucous membranes. Newborns with persistent central cyanosis, regardless of HR and respiratory effort, require supplemental oxygen and may require BVM and endotracheal intubation, depending on the etiology of the hypoxemia.

THE DISTRESSED NEWBORN

Following the initial assessment and resuscitation, the newborn will generally follow one of two paths—either being vigorous and requiring no further intervention other than close observation; or exhibiting signs of “distress,” mandating further resuscitative efforts. One situation that precludes normal resuscitation is that of meconium in the amniotic fluid.

Meconium staining of the amniotic fluid (MSAF) generally implies fetal distress. It is found in approximately 12% of all deliveries, predominantly in small-for-gestational-age (SGA) and post-term–stressed newborns. It is clinically important to avoid meconium aspiration which can result in meconium aspiration syndrome with

the following complications (hypoxemia, acidosis, and persistent pulmonary hypertension) (1,3).

The practice of suctioning the mouth, pharynx, and nose as soon as the head is delivered (intrapartum suctioning) is no longer recommended. The 2010 AHA/AAP/ILCOR guidelines (3) for management of the newborn with MSAF are as follows: After the body delivers, the appropriate management of the airway depends not only on the presence of meconium but especially on the newborn's level of activity (i.e., vigorous vs. nonvigorous). A vigorous newborn is defined as one who has strong respiratory effort, a HR greater than 100 beats/min and good muscle tone (7). In the vigorous infant with meconium, intubation and suctioning of the trachea is no longer recommended. Simply follow the routine postdelivery management protocol. However, if MSAF is noted and the newborn is nonvigorous (i.e., with depressed or absent respirations, depressed muscle tone, and/or a HR less than 100 beats/min) direct suctioning of the trachea is indicated as soon as possible, ideally before respirations have occurred. In this scenario the oropharynx and hypopharynx are first suctioned and then the trachea is intubated under direct visualization, allowing meconium to be suctioned from the lower airway. This is accomplished by utilizing a meconium aspiration device, attached to the endotracheal tube (ETT) on one end, with a suction device attached to the other end. Suction (negative pressure) should not exceed 100 mm Hg when the suction device opening is occluded. Once occluded, the negative pressure is transmitted to the tip of the ETT, resulting in meconium being drawn up into the ETT. The entire device and ETT are then all withdrawn at the same time. Repeated intubation and suctioning can be performed until meconium is no longer recovered. After tracheal suctioning the newborn should be resuscitated like other infants. Because of the complexity of this procedure and the need for two individuals, it is recommended that ED physicians be familiar with the equipment needed, as well as the procedure (1–3).

ADVANCED RESUSCITATION

Distressed newborns may require ongoing resuscitation (Fig. 216.2). Following the initial evaluation, any newborn who has apnea, gasping or ineffective respirations, or HR less than 100 that does not respond to SOS requires ventilation. Remember, do not hesitate, ventilate. Use a BVM with 100% oxygen at 40 to 60 breaths/min. This is the recommended ventilatory rate when chest compressions are not indicated. Because the fetal alveoli are atelectatic and collapsed, the initial BVM "breaths" in a term newborn may require a higher pressure ($>$30 to 40 cm H_2O pressure) to establish adequate lung volumes, but all subsequent breaths should be delivered at the lowest possible pressure. Good chest rise should be observed; if not, reposition the infant's head and attempt ventilation again. It is important to ensure a good seal between the mask and the newborn's face, and if necessary, to use the two-person technique. An 8 F orogastric tube should be placed to prevent gastric distension if prolonged BVM is required. After 30 seconds of PPV, the HR should be reevaluated. If oxygen is not available, initiate PPV with room air, and if a mask is not immediately available mouth-to-mouth and nose ventilation, with appropriate precautions, may be utilized. Remember, however, that the tidal volume required is only about 5 mL/kg weight; air should be puffed from the mouth rather than blown from the lungs. Improvement in the HR should result. The HR is the first sign of adequate ventilation and oxygenation, and will rise immediately. Once the HR is greater than 100, observe for spontaneous, effective respirations and discontinue PPV once they occur. Further resuscitative efforts are based on the HR after 30 seconds of PPV. If the HR remains $<$100 after 30 seconds, continue PPV and note if the HR is less than 60, at which point, chest compressions should accompany PPV with 100% oxygen (11). After 30 seconds of chest compressions and ventilation, stop long enough to determine the HR (palpable umbilicus). Continue ventilation if pulse is palpable. If a pulse is not palpable, check the HR by auscultating the chest. Then continue resuscitation based on HR and ventilatory effort. Adjust oxygen concentration administration based on pulse oximetry.

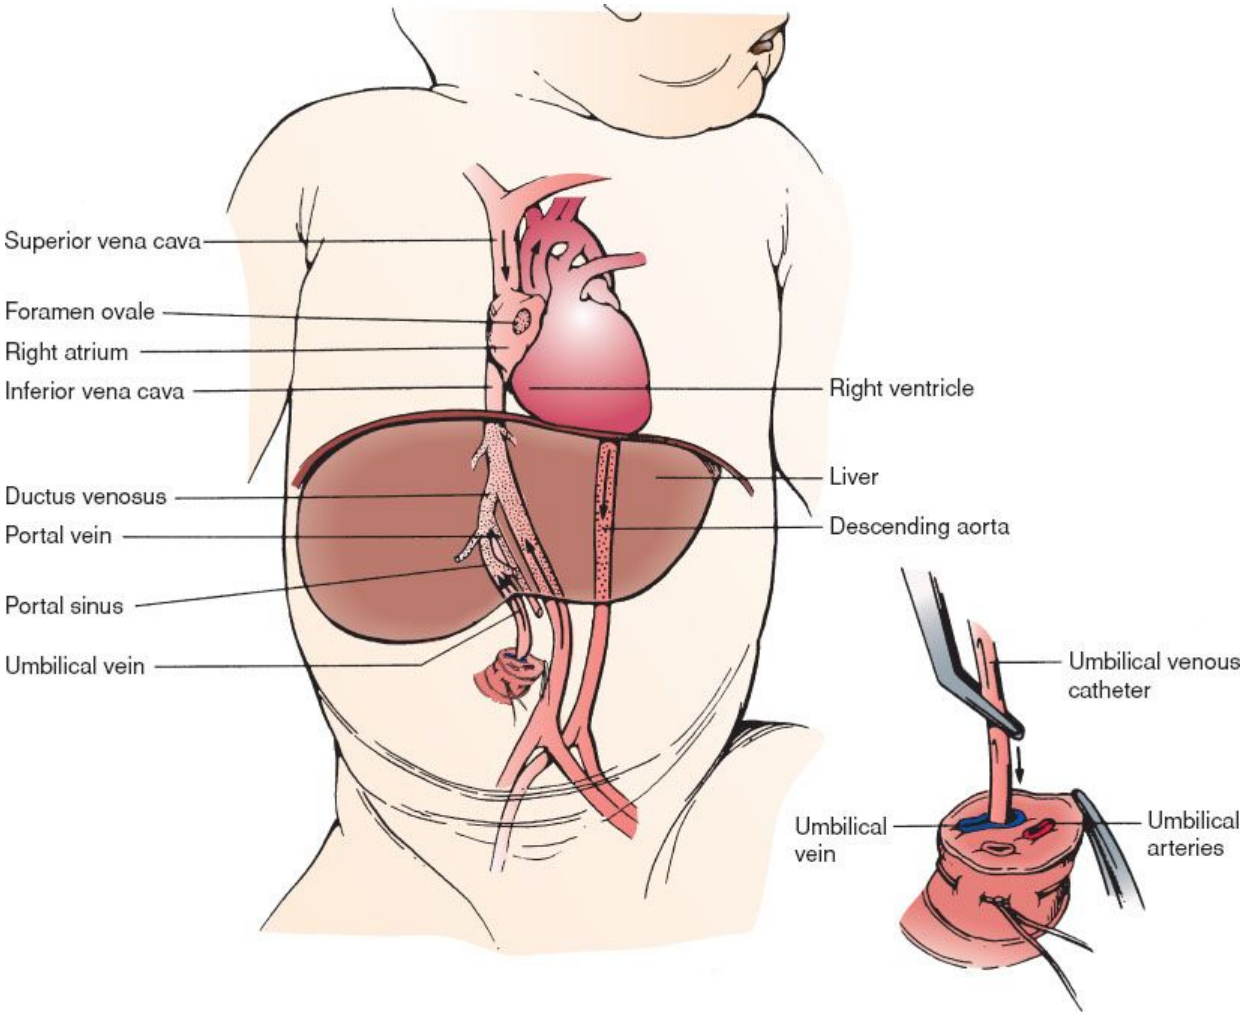

FIGURE 216.2 Insertion of the umbilical venous catheter.

Chest Compressions

Chest compressions should be initiated if: (1) absent HR at any time, (2) HR is less than 60 beats/min despite adequate assisted ventilation for 30 seconds. PPV must always be continued during chest compressions (1–3). The best technique for neonatal chest compression utilizes both thumbs placed on the lower third of the infant's sternum, with the resuscitator's hands encircle the newborn's torso with the fingers supporting the spine. Pressure is applied to the lower third of the sternum, between the nipple line (12). The sternum should be depressed one-third of the total diameter of the chest, accompanied by PPV at a rate of one ventilation for every three compressions; this delivers 90 chest compressions and 30

ventilations per minute. Chest compressions should be smooth, with the thumbs not leaving the infant's sternum between compressions and sufficiently deep to generate a palpable pulse. Care should be taken to avoid applying pressure to the xiphoid process, as this may injure abdominal organs. Compressions may be discontinued when the newborns' spontaneous HR exceeds 60 beats/min. The 2010 ILCOR working group agrees that *ventilation should be the priority in resuscitation of the newborn, and that chest compressions are likely to compete with ventilation.* Therefore, ventilations and compressions should be coordinated to optimize the resuscitation. Note that during chest compressions the ventilatory rate is 30 breaths/min, and not the 40 to 60 breaths/min used before chest compressions are started.

Endotracheal Intubation

Tracheal intubation is necessary: (1) whenever BVM is ineffective or prolonged, (2) when tracheal suctioning for meconium is required, (3) when chest compressions are performed, (4) when a congenital diaphragmatic hernia is suspected, (to avoid gastric distension) and (13) may be indicated after birth of an extremely low–birth-weight premature infant with inadequate ventilatory effort. Equipment size for intubation can be selected based on the infant's estimated weight and gestational age (Table 216.5). In general, premature newborns require a 2.5-mm ETT, whereas term newborns need a 3- to 3.5-mm ETT. A laryngoscope with a straight (Miller) blade (size 0 for premature, size 1 for term infants) is used to visualize the newborn's glottis and vocal cords. If a stylet is used, care must be taken to prevent the tip from protruding beyond the end of the ETT and injuring the airway. After intubation, proper ETT placement should be determined by careful physical examination, capnography or end tidal CO_2 monitoring (exhaled CO_2 detection) (14), and chest radiograph. Lack of chest rise, asymmetry of chest movement, and the lack of an increase in HR and/or color are signs of ineffective ventilation or a misplaced ETT.

TABLE 216.5
Equipment Size Based on Estimated Age and Weight

Age (wk)	Weight (kg)	ETT (mm)	Insertion Depth (cm)	Blade
<28	<1	2.5	7	0
28–34	1–2	3.0	8	0
35–38	2–3	3.5	9	0–1
>38	>3	3.5–4.0	10	1

The laryngeal mask airway (LMA) may be an effective alternative when used by appropriately trained providers in selected newborns (13). Masks that fit over the laryngeal inlet have been developed and found effective for ventilating full-term newborns, but have not been evaluated in small preterm newborns or those with meconium aspiration syndrome.

PHARMACOTHERAPY

Medications are rarely indicated during a newborn resuscitation and are reserved for specific situations (1,3,15). They are only utilized after unsuccessful resuscitative efforts initially focused on ventilation, oxygenation, and chest compressions. Epinephrine is the primary drug for asystole or bradycardia (HR less than 60) when there is a poor response to PPV with 100% oxygen and chest compressions for a minimum of 30 seconds. Occasionally, volume expansion is indicated, utilizing 10 mL/kg of crystalloid (normal saline, lactated Ringer). Volume is given by slow intravenous push, usually over 5 to 10 minutes. Five percent albumin has no advantage over crystalloid (15). The dose may be repeated after further clinical assessment.

Naloxone is no longer recommended when there is severe respiratory depression associated with a history of maternal narcotic administration. Naloxone can precipitate immediate severe withdrawal signs and should not be used in newborns born to mothers suspected of *chronic* opioid use. Current management is standard resuscitative measures, including ventilation.

Sodium bicarbonate (4.2%) is almost never indicated (16). If utilized, it should only be administered during a prolonged arrest unresponsive to standard measures where a severe metabolic acidosis is documented. Sodium bicarbonate may worsen respiratory acidosis and may induce hyperosmolality; it should not be a substitute for adequate ventilation.

Glucose ($D_{10}W$) should be administered in a dose of 2 to 4 mL/kg intravenously (IV) for documented or symptomatic hypoglycemia (less than 30 mg/dL in preterm, less than 40 mg/dL in term newborns).

A dopamine infusion (5 to 20 μg/kg/min IV continuous) should be considered when signs of shock continue despite volume expansion. High-dose epinephrine is not recommended in newborn resuscitations (Table 216.6).

TABLE 216.6
Medications

Medication	Concentration	Dose	Route
Epinephrine	1:10,000	0.1–0.3 mL/kg	IV recommended
Volume expanders	Normal saline Ringer lactate O-negative blood	10 mL/kg	IV
Glucose	$D_{10}W$	2–4 mL/kg	IV
Dopamine	Continuous IV infusion at 5–20 μg/kg/min		

VASCULAR ACCESS

When intravenous access cannot be established, the umbilical vein is the most accessible site. Using sterile technique, a tie is placed around the base of the umbilical stump to control bleeding, and a scalpel is used to cut the cord 0.5 to 1 cm above the skin. *The umbilical vein (always at the 12:00 o'clock position towards the head) is easily distinguished from the two smaller arteries, which are usually constricted.* Flush a sterile 3.5 F (premature) or 5 F (term) umbilical venous catheter with normal saline and attach it to a three-way stopcock. The catheter is advanced into the umbilical vein just below

the skin level until good blood return is obtained (usually of 2 to 4 cm). Wedged hepatic positions are recognized by subsequent failure of free blood return after introduction. If this occurs, the catheter should be withdrawn to a position where blood can be easily aspirated. Secure the umbilical venous catheter to the skin with tape (Fig. 216.2). When other means of vascular access are not available, the intraosseous route may be attempted; however, its use is not common in this age group (17).

FAILURES OF RESUSCITATION: SPECIAL SITUATIONS IN NEWBORN RESUSCITATION

If the newborn is not responding to resuscitative measures, other causes must be considered and sought. Generally, the etiology of the "failures" fall into one (or more) of five categories: (1) technical problems, (2) unrecognized pulmonary problems, (3) congenital anomalies of the organ systems involved, and, (4) severe anemia and (5) severe metabolic problems (Table 216.3).

"Technical Problems" are by far the most common, and of these, inadequate ventilation is the most frequent. This is either because the airway is not opened adequately, poor position of the head, poor seal of the mask to the face, or (if the patient has been intubated) malposition of the ETT. Airway repositioning may solve the problem. In intubated patients, the ETT may be in the esophagus or it may have been advanced into the right main stem bronchus. First, check the tube position by laryngoscopy or reintubating the newborn. If the tracheal tube is in correct position, chest expansion should be seen with ventilation, the HR should rise, and the oxygen saturation should increase. Another possible cause of poor air entry is pneumothorax, which may occur on either side. PPV with esophageal intubation may result in "apparent" air entry when auscultating the lungs; however, the chest will not move and air will be heard entering the stomach. Therefore, one should auscultate both lungs in the axilla and the epigastric area for confirmation of initial ETT placement and position.

Other technical problems include inadequate oxygen flow, pressure, concentration, or a "malfunctioning" ventilation system. If

there is an inadequate response, increase the oxygen concentration to 100%, with enough flow and pressure to generate chest wall movement. Excessive pressures are harmful, yet adequate pressure must be administered for ventilation to occur.

The second category of failures is unrecognized pulmonary problems. Although these must be suspected clinically, many are ultimately confirmed radiologically. Problems such as pneumothorax, diaphragmatic hernia, hypoplastic lungs, intrauterine pneumonia or sepsis, pleural effusion (hydrops fetalis), and other severe restrictive lung problems may result in an "unresuscitatible" infant.

Those born with hypovolemia or severe anemia secondary to placenta previa or abruptio placenta, are frequently unrecognized and may be unresponsive to appropriate resuscitative techniques. The most common problems include hypothermia, hypoglycemia, and severe metabolic acidosis. All will interfere with resuscitative efforts and therefore must be recognized and treated.

Infants born with congenital or acquired conditions involving the lungs, airway, heart, central nervous system, neuromuscular system, or hematopoietic system may not respond to resuscitation. Persistent central cyanosis may be secondary to cyanotic congenital heart disease, whereas persistent bradycardia may be secondary to heart block. Radiographic and other evaluations are frequently required to make the diagnosis.

POSTRESUSCITATIVE CARE AND DISPOSITION

Early consultation (including the physical presence) of a neonatologist or pediatrician is ideal to assist with resuscitation and determine the level of postresuscitative care needed. Depending on the etiology and on the degree of resuscitation required, the newborn will now require 1 of 3 levels of care: routine (standard observation), supportive (frequent evaluation), or ongoing care (continuing evaluation and monitoring in an NICU environment). If transfer is required, it is best accomplished by a tertiary care facility with a newborn transport team.

Following stabilization of the newborn, special care should be taken to maintain temperature and euglycemia, and to monitor

respiratory rate and effort, oxygen saturation, administered oxygen concentration, HR, blood pressure, and muscle tone or activity. Newborns remaining in the ED for any prolonged time should have labs sent, including CBC, arterial blood gas (ABG), glucose and calcium levels. A chest x-ray to assess ETT placement and to rule out occult pathology is recommended. If needed, the newborn can be ventilated at a rate of 40 to 60 breaths/min with end tidal CO_2 and pulse oximeter monitoring until the ABG and results are obtained. Maintenance intravenous fluids can be started with $D_{10}W$ at 80 mL/kg/d, as electrolytes are generally not required in the first 24 hours of life. Lorazepam 0.1 mg/kg (or equivalent) is effective to sedate the intubated newborn if needed. In addition, treatment of possible infection, seizures, or hypotension (with volume expanders or inotropes), and documentation of resuscitation are indicated. The parents must be informed of the newborn's condition and must be allowed to see and touch the baby, with their questions answered as frankly and honestly as possible.

DISCONTINUING RESUSCITATIVE EFFORTS

When the newborn demonstrates no signs of life (no respiratory effort, no heartbeat) after 10 minutes of effective continuous resuscitation, outcomes are dismal. The rare survivor whose heartbeat returns after this period of time will most likely have suffered severe anoxic encephalopathy and hypoxemic tissue and organ damage, with severe morbidity and high likelihood of early mortality (1–3,18).

In most cases it is advisable for the parents to be present in the resuscitation room to become actively involved with the decision to discontinue resuscitation and, if desired, to allow the newborn to die in the arms of the mother.

CRITICAL INTERVENTIONS

- Develop newborn resuscitation preparation plans or policies covering equipment, medications, contact information (NICU,

transport team, labor, and delivery, etc.), mock resuscitation drills, and staff education
- Obtain critical historical elements as soon as possible (multiple births, prematurity, meconium, vaginal bleeding, or maternal drug use)
- Continually reassess HR, respirations, and color after each intervention
- Remember the practical and the resuscitation basics, suction, oxygen, and stimulation (SOS), and do not hesitate—ventilate

Common Pitfalls

- Failure to have specific newborn resuscitation equipment set-up and readily accessible, including a radiant warmer.
- Lack of individuals with the skills required to perform a complete newborn resuscitation
- Failure to recognize the "high-risk" mother or fetus.
- Failure to initiate basic resuscitation techniques, especially ventilation.
- Failure to recognize the newborn with secondary apnea, thus delaying the initiation of PPV.
- Failure to adequately clear meconium from the hypopharynx and trachea before stimulating the nonvigorous newborn.
- Failure to consider "other causes" in a nonresponsive newborn (Table 216.3).
- Delay in initiating SOS and do not hesitate to ventilate!

CHAPTER 217

Pediatric Resuscitation

Stephanie J. Doniger

The resuscitation of pediatric patients may be especially challenging to emergency care providers. In approaching pediatric resuscitations it is crucial to identify early decompensation and respond promptly. Successfully applied techniques of basic and advanced life support are crucial to reducing childhood mortality. The goal of resuscitation is to urgently re-establish delivery of substrate to meet the metabolic demands of vital organs, particularly the brain (1).

In contrast to adults, the majority of cardiac arrests in children result from a progression of shock and respiratory failure to circulatory arrest. The most common causes of unexpected death in children are trauma, sudden infant death syndrome (SIDS), respiratory causes, cardiovascular causes, and submersion (2). In patients older than 1 year, injury is the most common cause of death. While survival from traumatic arrest is rare, targeted intervention and prevention are emphasized in the newest American Heart Association (AHA) pediatric guidelines (3). It is estimated that in the United States there are 2.6 to 19.7 out-of-hospital pediatric cardiac arrests per 100,000 children each year. The incidence of in-hospital pediatric cardiac arrest is unknown. Reported survival rates to hospital discharge after an out-of-hospital or in-hospital arrest are approximately 6% and 27%, respectively (4). Approximately 50% to 65% of children requiring cardiopulmonary resuscitation (CPR) are less than 1 year of age, and the majority are less than 6 months old.

The year 2010 marked the 50th anniversary of CPR, and its newest guidelines were published. The majority of changes focused on the administration of quality compressions, and the education and

training of providers (5). Training and education can be greatly enhanced by the use of simulation, which has been shown to improve performance during actual resuscitations (5). The previously taught sequence of “ABC” or “airway-breathing-chest compressions (circulation)” was changed to “CAB” or “chest compressions-airway-breathing” to reflect the importance of quality compressions during CPR. This is also because the vast majority of victims requiring CPR are adults in cardiac arrest due to ventricular fibrillation, in whom compressions are crucial. It is also generally easier to start compressions immediately, while administering ventilations requires preparation and patient positioning (6). It is important to note, however, that since the majority of pediatric cardiac arrests are secondary to asphyxial, rather than cardiac causes, it may be prudent to employ the original “ABC” algorithm.

For the lay rescuer, pediatric guidelines are applied to children from 1 to 8 years of age, and adult advanced cardiac life support (ACLS) guidelines to those more than 8 years old. For the advanced provider, pediatric advanced life support (PALS) guidelines can be applied to children 1 year of age through the onset of puberty, which is typically 12 to 14 years of age. The 2010 guidelines further specify that signs of puberty in a female includes breast development, while in males includes the presence of axillary hair (6).

Despite the use of CPR and improved resuscitation techniques, mortality rates resulting from cardiac arrest are as high as 90% to 97% for infants and children. For respiratory arrest alone, the mortality rate is nearly 25%. In cases with survival, children may suffer from severe neurologic deficit.

CLINICAL PRESENTATION AND ASSESSMENT

In contrast to adults who require resuscitation, cardiovascular collapse in children is generally the result of respiratory decompensation. Children may first present with subtle abnormalities in vital signs or may exhibit frank signs of respiratory distress. It is crucial to recognize deviations from age-appropriate vital signs early, so that unanticipated cardiovascular failure can be avoided. (**Tables 217.1–217.3**).

TABLE 217.1
Expected Respiratory Rates, According to Age

Age (yr)	Breaths (per min)
<1	30–60
1–3	24–40
4–5	22–34
6–12	18–30
13–18+	12–16

TABLE 217.2
Expected Heart Rates, According to Age (20)

Age	Rate beats/min (mean)
0–3 mos	80–205 (140)
3 mos–2 yr	75–190 (130)
2–10 yr	60–140 (80)
>10 yr	50–100 (75)

Adapted from Ralston M, Hazinski M, Zaritsky A, et al. Pediatric Assessment. *PALS Provider Manual.* Dallas, TX: American Heart Association; 2006:1–32.

TABLE 217.3
Expected Systolic and Diastolic Blood Pressures According to Age

Age	Systolic Blood Pressure (mm Hg)	Diastolic Blood Pressure (mm Hg)
0 d	60–76	30–45
1–4 d	67–84	35–53
1 mo	73–94	36–56
3 mos	78–103	44–65
6 mos	82–105	46–68
1 yr	67–104	20–60
2 yr	70–106	25–65
7 yr	79–115	38–78
15 yr	93–131	45–85

NOTE: Females have slightly lower systolic blood pressures and slightly higher diastolic blood pressures when compared with males of the same age.
Adapted from Ralston M, Hazinski M, Zaritsky A, et al. Pediatric Assessment. *PALS Provider Manual.* Dallas, TX: American Heart Association; 2006:1–32.

Early signs of respiratory distress in children may include nasal flaring, retractions or accessory muscle use, or irregular respirations. Signs of airway obstruction include breathing difficulty, the inability to speak or breathe, poor air exchange, a silent cough, or poor air exchange. On auscultation of the lungs, abnormal sounds include stridor, grunting, gurgling, wheezing, and crackles.

The assessment of cardiovascular function primarily includes heart rate and rhythm and blood pressure. Indicators of adequate perfusion include peripheral and central pulses, capillary refill time, and skin color and temperature. A delayed capillary refill time (>2 seconds) represents poor peripheral perfusion and may be the result of dehydration, shock, or hypothermia.

Heart rate varies according to the child's age, and the normal range is wide (Table 217.2). Typically, the rate is slower in a sleeping or athletic child. Bradycardia, which is a heart rate less than that expected for a child's age, may be attributed to vagal stimulation, hypoxemia, acidosis, or an acute elevation of intracranial pressure. Other serious etiologies can include first-, second-, and third-degree heart block. Complete heart block, acquired or congenital, is a common cause of significant bradycardia in pediatric patients. However, the most common cause of bradycardia in the pediatric population is hypoxemia.

Tachycardia is defined as a heart rate greater than that expected for a child's age. The vast majority of pediatric tachycardias are supraventricular in origin. Tachycardias of ventricular origin are typically associated with significant hemodynamic compromise.

Normal blood pressures also vary according to age (Table 217.3). Hypotension is defined as below the fifth percentile of expected blood pressures for age. Hypotension may be due to hemorrhage, sepsis, or cardiac failure.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

The newer 2010 AHA guidelines recommend initiating chest compressions early, as the first step of the resuscitation sequence, except when arrest is caused by asphyxia.

It is important to approach the evaluation and management in a stepwise manner. It has been traditionally taught that the airway is assessed first, then breathing, and finally circulation (ABC). If there is an abnormality at any step of this ABC assessment, intervention must be initiated at that point. The newer 2010 AHA guidelines recommend initiating chest compressions early, as the first step of the resuscitation sequence, except when arrest, is caused by asphyxia. In single bystander rescuer resuscitation, or basic life support (BLS), compressions alone may be sufficient in nonasphyxial arrests. While the traditional teaching for PALS is a stepwise approach, for in-hospital cardiac arrests, there is usually a team present, where each member can perform components of the resuscitation concurrently.

Early initiation of high-quality CPR and early defibrillation appear to improve overall survival from arrest. Only one-third of out-of-hospital cardiac arrest victims receive CPR prior to the arrival of emergency medical service (EMS) (4), and those who do receive it often do not receive effective CPR. Suboptimal CPR is often characterized by chest compressions that are too few, too shallow, and too weak. In addition, patients are often overventilated and there are too many interruptions in chest compressions (7).

CIRCULATION

Either the intravenous (IV) or intraosseous (IO) route is used for vascular access and for the administration of drugs. Peripheral IV placement may be difficult in a critically ill child. An IO line, especially with the advent of rapid guns for their insertion, is preferred to the placement of a central line. Central line placement requires time and expertise. However, the safety and success of central line placement can be improved with the use of ultrasound guidance. When other routes of vascular access are unavailable, lipophilic drug delivery may be performed via the ETT. These drugs include "LEAN": lidocaine, epinephrine, atropine, and naloxone (Narcan) (8). The drugs need to be administered at higher doses, generally two to three times their IV dosing. Epinephrine is recommended to be 10 times the IV dosing, and atropine 0.04 to 0.06 mg/kg. This route, however, is unpredictable and is *not* recommended.

Rhythm abnormalities must be recognized and treated appropriately. The heart rhythm can initially be assessed as either regular or irregular, or too fast or too slow. It is crucial to determine whether a pulse is present with the associated rhythm. Unfortunately, it has been shown that pulse checks are often difficult and unreliable. Bedside ultrasound is helpful in determining the presence of cardiac activity.

For patients with bradycardia, defined as a heart rate <60 beats per minute, providers must support oxygenation and ventilation and perform CPR. One must search for and correct underlying causative abnormalities and promptly initiate pharmacologic therapy as necessary.

For tachycardia, stepwise questioning can help the evaluation. Is the rhythm regular or irregular? Is the QRS narrow or wide? Does every P result in a single QRS? The important tachydysrhythmias to recognize are ventricular fibrillation, ventricular tachycardia, pulseless electrical activity (PEA), asystole, and supraventricular tachycardia. For PEA, it is important to identify and treat possible causes. Bedside ultrasound may readily identify some reversible causes of PEA and arrest, such as cardiac tamponade.

Compressions

Effective chest compressions are crucial in improving survival. Compressions provide blood flow to vital organs such as the heart and brain and allow for the return of spontaneous circulation. The AHA recommends to "push hard and push fast." Interruptions in compressions should be limited to <10 seconds for interventions such as placing an advanced airway or defibrillation. *Interruptions in compressions have been shown to decrease the rate of return of spontaneous circulation.* Rhythm checks should be performed every 2 minutes, or every five cycles of CPR. Once an advanced airway is in place, compressions and ventilations should be performed continuously without interruption.

Previous studies show that 92% of chest compressions delivered during in-hospital resuscitation were less than the recommended depth (9). A recent study further showed that 20% of the time, compressions are administered at double the recommended rates in in-hospital pediatric arrests (10). In order to perform adequate compressions for children, the heel of one or two hands can be used to compress the lower half of the sternum to a depth of at least one-third of the anteroposterior diameter of the chest, or approximately 2 inches (5 cm) in children and 1.5 inches (4 cm) in infants. This depth provides an associated systolic blood pressure >80 mm Hg and diastolic blood pressures >30 mm Hg during CPR in children (11). For infants, the AHA recommends that two thumbs press on the sternum, with the hands encircling the chest. This technique improves coronary artery perfusion pressure and may generate higher systolic and diastolic blood pressures. There is insufficient evidence to suggest an additional circumferential squeeze of the thorax (3). In order to prevent rescuer fatigue, rescuers should be changed after five cycles of CPR, or every 2 minutes. To minimize interruptions in CPR this switch should be performed in less than 5 seconds.

In patients without a pulse, and in children with a heart rate <60 beats per minute, chest compressions should be initiated. Because bradycardia is often a terminal rhythm in children, one should not

wait for pulseless arrest to occur before initiating compressions. For children of all ages, except newborns, compressions should be performed at a rate of 100 per minute. The compression to ventilation ratio is 30:2 for single rescuers, and the ratio is 15:2 for two-rescuer resuscitation (6). These universal rates simplify guidelines for providers, and they allow for sufficient time for adequate chest recoil to permit cardiac filling and venous return (12).

Defibrillation

With witnessed arrest due to ventricular fibrillation, immediate defibrillation is warranted. This action is followed by CPR and drug administration. CPR provides some blood flow, delivering oxygen and substrate to the heart, making reversal of ventricular fibrillation more probable. A single shock should be administered at a dose of 2 J/kg, followed by immediate CPR. Ventricular fibrillation is terminated by the first shock in at least 90% of cases (13). For children less than 1 year of age or less than 10 kg pediatric-specific paddles or pads *must* be used. It is important to use the self-adhesive pad or electrode gel. Do not use saline-soaked pads, ultrasound gel, bare paddles, or alcohol pads. While manual defibrillation is preferred, if unavailable, an automated external defibrillator (AED) with a dose attenuator may be used. If neither are available, an AED may be used and does not lead to myocardial damage (1).

CPR is beneficial immediately post defibrillation. CPR appears to "prime" the heart for the next defibrillation attempt. In cases of prolonged ventricular fibrillation, it has been shown that giving CPR prior to defibrillation increases survival rates from 4% to 22% (14). Defibrillation is performed with energy of 2 J/kg, followed by 4 J/kg for subsequent dosages, regardless of the type of defibrillator. "Stacked" shocks are no longer recommended because of the time required to administer three shocks in a row, during which CPR is not being provided. A single shock, followed by CPR, is recommended. CPR should not be interrupted for a pulse or rhythm check until five cycles or 2 minutes.

The treatment of each rhythm disturbance should proceed according to the tachycardia algorithm (Fig. 217.1); with the presence or absence of a pulse, determining which arm of the algorithm is followed. Sinus tachycardia with adequate perfusion is no longer included in the algorithm. Polymorphic ventricular tachycardia is now considered an unstable rhythm that requires the use of unsynchronized, rather than synchronized, shocks. Low-energy synchronized shocks are felt to risk provoking ventricular fibrillation (1).

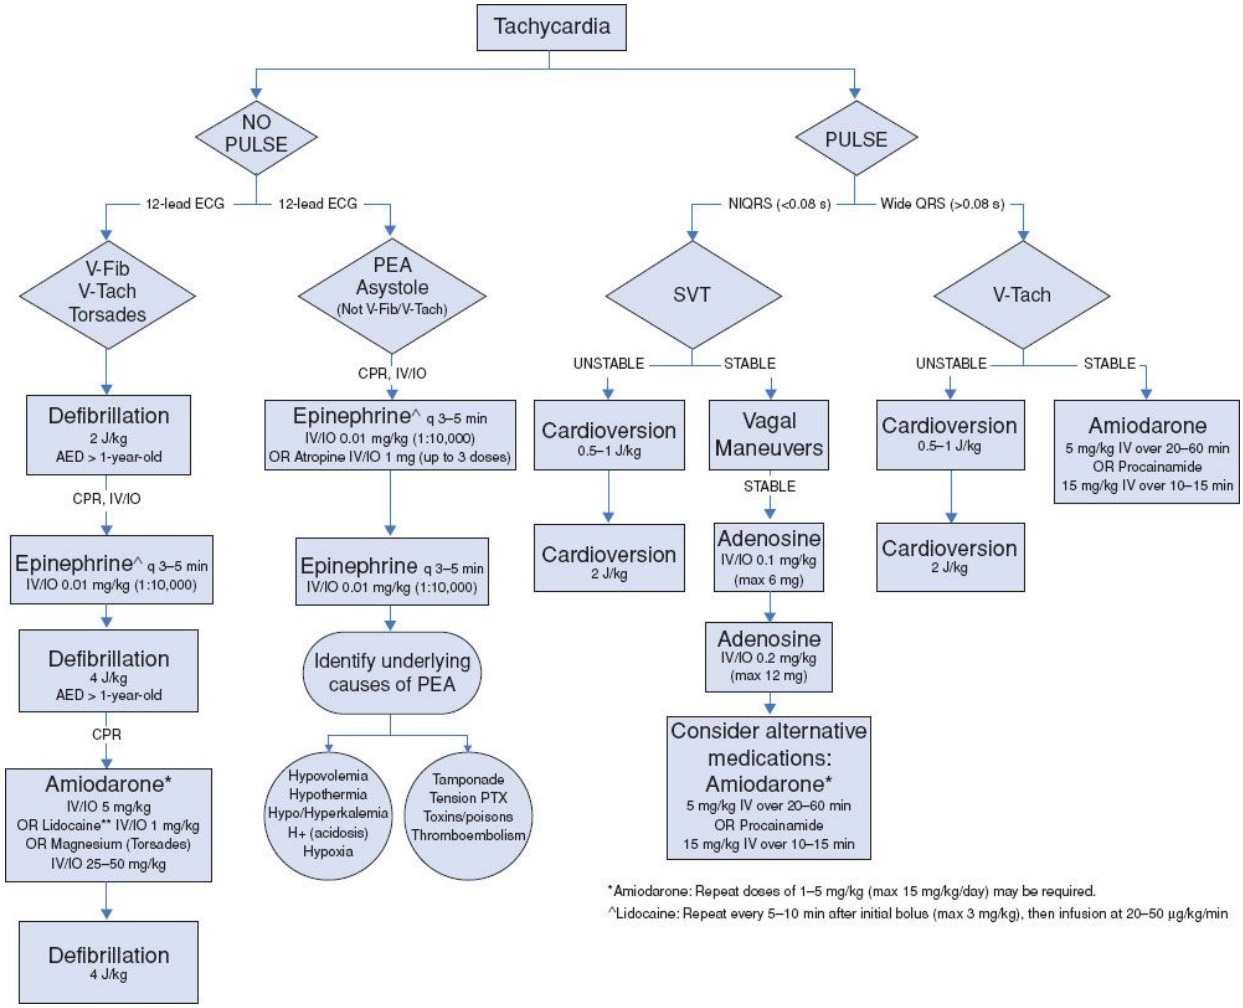

FIGURE 217.1 Tachycardia algorithm. (Adapted from Ralston M, Hazinski M, Zaritsky A, et al. Pediatric Assessment. *PALS Provider Manual*. Dallas, TX: American Heart Association; 2006:1–32.)

Community use of AEDs has been shown to increase survival rates, and there is evidence that they can safely be used in patients greater than 1 year of age (15). The AED should be used as soon as possible after a sudden witnessed collapse. If the collapse is unwitnessed, CPR should be performed for five cycles, or 2 minutes, prior to the use of the AED. Energy levels should be adjusted for age. If the pediatric dose is unavailable, the adult dose is a reasonable alternative.

Pharmacologic Therapy

For the most part, the algorithm drug dosages remain the same in the updated 2010 AHA guidelines. Dosing for medications has been controversial; the current recommendations suggest utilizing the patient's actual weight, rather than the ideal body weight. Tape-based methods (such as Broselow) have been validated and shown to be more accurate than estimation by providers. Drug delivery should not interrupt CPR. The timing of drug delivery is less important than minimizing chest compressions.

For pharmacologic treatment of bradycardia, epinephrine (IV/IO 0.01 mg/kg, ETT 0.1 mg/kg) should initially be administered and can be repeated every 3 to 5 minutes. In situations of a primary atrioventricular (AV) block or increased vagal tone, atropine is recommended (initial dose 0.02 mg/kg, minimum dose 0.1 mg, maximum dose 1 mg) and may be repeated (16). Epinephrine and isoproterenol infusions are no longer recommended to treat refractory bradycardias.

In cases of asystole or PEA, one should initiate immediate CPR. CPR is followed by epinephrine (0.01 mg/kg IV/IO). Alternatively, atropine may be administered (1 mg IV/IO, 0.04 to 0.06 mg/kg ETT). For PEA in particular, it is important to identify and treat underlying causes.

High-dose epinephrine (1:1,000 concentration via IV) is not recommended in any age group and is associated with a worse outcome, especially in cases of asphyxia (17). Therefore, the standard recommended dose is 0.01 mg/kg IV/IO, which correlates to 0.1 cc/kg. Though the preferred routes of administration are IV or IO, it may be given via the ETT at 10 times the IV dose, when other

access is unable to be obtained (0.1 mg/kg ETT) (18). In exceptional cases, such as β-blocker overdoses, high-dose epinephrine may be considered.

Amiodarone is the preferred drug for the treatment for pulseless arrest. Lidocaine is recommended only when amiodarone is unavailable and is no longer listed on the AHA stable ventricular tachycardia algorithm (16), having been replaced by amiodarone and procainamide. Amiodarone and procainamide should not be administered together, as they can lead to severe hypotension and prolongation of the QT interval.

The routine use of calcium and sodium bicarbonate is not recommended. Sodium bicarbonate in particular may impair tissue oxygen delivery, induce electrolyte abnormalities, and decrease the VF threshold. However, both calcium and sodium bicarbonate may be indicated in special situations such as toxidromes (1). Sodium bicarbonate may be indicated for tricyclic antidepressant or sodium channel blocker overdoses, while calcium may be indicated for a calcium channel blocker overdose. Calcium gluconate may be preferable than calcium chloride since it causes a greater increase in ionized calcium.

Airway

The first priority in basic and advanced life support for children is evaluation of the airway. In order to assess upper airway patency, the provider should look for chest rise, listen for breath sounds and air movement, and feel the movement of air at the nose and mouth. It is crucial to determine whether the airway can be maintained by simple maneuvers; if not, advanced interventions are necessary.

If the airway is not patent, simple measures to restore patency should be tried first: changing the patient's position, suctioning, and attempting to relieve foreign body obstruction. For the latter, the recommendation is to perform five back blows and five chest thrusts in infants and to perform the Heimlich maneuver in older children. If a patient is unresponsive, it is recommended to activate EMS and to begin performing CPR. For the lay rescuer, the preferred method of opening the airway is the head tilt–chin lift maneuver. It is

unadvisable to perform blind finger sweeps, and it is not recommended to perform the "jaw thrust" maneuver, because this technique is difficult to learn and perform and is often ineffective, especially for inexperienced providers. In trauma situations, especially when a cervical spine injury is suspected, jaw thrust maneuver without head tilt is the maneuver of choice to open the airway (16).

Patients who do not exhibit adequate breathing should receive rescue breaths. It is recommended to try to deliver two effective rescue breaths. In patients who are not breathing but have a pulse, respirations should be delivered without compressions. The provider should administer 12 to 20 breaths/min (1 breath every 3 to 5 seconds) for infants and children (6). Breaths should be given over 1 second in order to avoid hyperventilation and gastric inflation.

The method of maintaining the airway depends on the provider's skill level. For those untrained in advanced airway skills, the focus must be on effective bag valve mask (BVM) technique. A two-person BVM technique can be utilized in situations of airway obstruction, poor lung compliance, or when the rescuer has difficulty in creating an adequate seal. Airway adjuncts such as oropharyngeal and nasopharyngeal airways may assist in opening the airway and facilitating the delivery of oxygen by bag valve mask.

For those skilled in its use, endotracheal intubation is the preferred way of securing an airway with rapid sequence intubation (RSI) (see Chapter 218). It is now recommended that a cuffed endotracheal tube (ETT) may be used in all ages except neonates. The cuffed tube is especially useful for those patients with poor lung compliance, increased airway resistance, or a large glottic air leak. Attention must be paid to tube size, position, and pressures. For children less than 1 year of age, a 3-mm cuffed ETT may be used. For children 1 to 10 years of age, the endotracheal size can be calculated by the following formula (19).

The size of an uncuffed ETT is determined by:

$$\text{Size (mm internal diameter [ID])} = (\text{age in years}/4) + 4$$

For a cuffed ET, subtract 0.5 from the size to obtain the appropriate-sized tube. The appropriate depth of placement of the ETT is roughly estimated as three times the ID of the ETT. ETT cuff pressure should be maintained at <20 cm H_2O (20).

ETT placement should be confirmed by the auscultation of breath sounds. It is recommended to measure exhaled CO_2 by a colorimetric detector or by capnography. However, these devices are effective only in patients with a perfusing rhythm. In patients weighing more than 20 kg, one may consider use of an esophageal detector device to confirm tube placement (21). It is important to repeatedly verify ETT position immediately after the tube is inserted, during transport, and after movement of the patient as ETTs may become dislodged. When endotracheal intubation is not possible, a reasonable alternative is the placement of a laryngeal mask airway (LMA). However, the placement of LMAs are associated with a higher incidence of complications in children (22).

During the process of providing breaths and intubating a patient, gastric inflation is common with subsequent vomiting. In order to decrease gastric inflation, it is recommended to avoid excessive peak inspiratory pressures, but ventilating slowly and only giving enough tidal volume to create visible chest rise. Cricoid pressure may be utilized, but care must be taken to avoid excessive cricoid pressure, which may cause tracheal obstruction. Finally, a nasogastric or orogastric tube may be utilized to decompress the stomach. In situations where a child has a gastrostomy tube in place, it may be vented to relieve gastric inflation (16).

Breathing

The assessment of breathing includes an evaluation of the respiratory rate and effort, lung sounds, and pulse oximetry. Further factors to assess are adequacy and equality of chest wall excursion and the amount of air movement.

Once an advanced airway is in place, respirations should be administered simultaneously with chest compressions, at a rate of 8 to 10 per minute. Note this rate is markedly lower than previous

recommendations. Hyperventilation is not recommended and can be harmful (23). Increased respiratory rates tend to produce cause increased intrathoracic pressure, which reduces venous return and coronary perfusion pressure. Rescue breaths that are administered at a high rate create increased intrathoracic pressure, which reduces venous return and coronary perfusion pressure. Fewer breaths and smaller volumes are needed for oxygenation and ventilation because there is significantly less blood flow to the lungs during CPR (16). The most recent AHA guidelines discuss the possible adverse effects of hyperoxia; they recommend performing resuscitation with 100% FiO_2, but once the patient is stabilized the FiO_2 may be reduced to maintain oxygen saturations of at least 94% (6).

Positive-pressure ventilation can be provided by the use of a self-inflating bag, a flow-initiating bag, or a T-piece device. The T-piece is a valved device that regulates pressure and limits flow. The best indicator of successful ventilation is an increase in the heart rate. Supplemental oxygen is recommended for patients receiving positive-pressure ventilation and who are breathing spontaneously but are cyanotic.

KEY TESTING

- Laboratory testing is usually not immediately available to impact immediate, life-saving, resuscitative efforts
- When available, point-of-care electrolyte, glucose, and blood gas testing may be helpful
- In PEA arrest, bedside ultrasound may be helpful in determining cardiac activity, cardiac tamponade, or unsuspected pneumothorax
- Postintubation portable radiographs are important to confirm ETT and central line placement
- For sepsis, CBC, blood cultures, and serum lactate may help in guiding therapy
- For traumatic arrests, CBC and type-and-screen may be indicated

CRITICAL INTERVENTIONS

- Effective CPR is crucial with limited interruptions.
- "Push hard, push fast" at 100 compressions/min.
- Universal compression: ventilation 30:2 (lone rescuer), 15:2 (two rescuers).
- Use cuffed or uncuffed ETT with attention to size, position, and pressures.
- Once advanced airway is in place, provide simultaneous ventilations and compressions with ventilation rate of 8 to 10 breaths/min.
- IV/IO is preferable to ETT for drug administration.
- Defibrillation: a single shock is followed by immediate resumption of CPR.
- Amiodarone is preferred for pulseless arrest due to ventricular fibrillation or ventricular tachycardia.

SPECIAL SITUATIONS

The newest AHA recommendations discuss special situations, including shock, trauma, known congenital heart disease, and special pediatric health care needs.

It is common for children to present in shock. However, it is often not recognized early enough. In septic shock, it is important to identify and intervene early, and consider providing early ventilatory assistance. In situations where a child in septic shock is intubated, one may consider the use of etomidate as an induction agent, since it causes minimal hemodynamic effects. However, etomidate has been shown to cause adrenal suppression and may lead to a higher mortality rate in septic shock, so alternative induction agents should be considered (1).

In traumatic arrests, common errors include the failure to open and maintain the airway, failure to provide appropriate fluid resuscitation, and the failure to recognize and treat internal bleeding. It is also important to maintain C-spine immobilization. It is ideal to open the airway with a jaw thrust, but when that is not possible, a head tilt–chin lift may be performed. For patients with maxillofacial trauma or a basilar skull fracture, an orogastric, instead of a nasogastric, tube should be utilized. Contrary to prior teaching, it is

not routinely recommended to hyperventilate, even with head injury. For trauma patients presenting in shock, one should consider and look for intra-abdominal hemorrhage, a tension pneumothorax, tamponade, or spinal cord injury as possible etiologies. A high suspicion for thoracic injury should be maintained with all patients with thoracoabdominal trauma. In those patients presenting with penetrating chest trauma, a thoracotomy should be considered (16). In addition, pressure should be applied to all external signs of hemorrhage and spinal motion should be prevented by securing the thighs, pelvis, and shoulders to an immobilization board. Whenever possible, children should be transported to a pediatric trauma center as rapidly as possible (3).

The newest 2010 AHA guidelines discuss the management for children with single ventricle physiology and pulmonary hypertension. For those children with a systemic to pulmonary artery shunt, or a right ventricle to pulmonary artery shunt, heparin should be considered, since a clotted-off shunt may be the cause of acute decompensation. It is important to maintain a careful balance between systemic and pulmonary blood flow, and to therefore maintain saturations greater than 80%, rather than the 94% target for children without congenital heart disease. It is important to note that $ETCO_2$ may not be reliable since pulmonary blood flow changes rapidly in this patient population. For those patients with a Fontan or hemi-Fontan/bidirectional Glenn, hypoventilation may improve oxygen delivery in those patients in a prearrest state. Finally, for those patients with pulmonary hypertension, standard PALS resuscitation guidelines should be initiated. One may attempt to correct the hypercarbia, and to administer IV fluids to correct preload. Inhaled nitric oxide or aerosolized prostacyclin may be considered in order to reduce pulmonary vascular resistance. When these inhaled agents are unavailable, IV prostacyclin may be considered as an alternative agent (16). In those situations where cardiac arrest is refractory to standard attempts, extracorporeal membrane oxygenation (ECMO) should be considered.

Children with special health care needs present frequently to the emergency department. Those patients requiring resuscitation can

present a particular challenge to providers. Patients with gastrostomy tubes should have the tube vented to prevent gastric inflation during ventilation assistance. In those patients with a tracheostomy or stoma present in respiratory distress, one may consider replacing the tracheostomy tube. When this is unsuccessful, ventilation may be performed directly through the stoma, or the stoma may be occluded while administering BVM breaths from above (16).

DISPOSITION

Postresuscitation goals are to stabilize and preserve neurologic function, and to prevent secondary organ injury. It is important to properly monitor patients (pulse oximetry, $ETCO_2$), assist ventilation, and confirm proper ETT placement, especially when the patient has been moved or transported. In order to reduce oxidative injury, saturations should be maintained greater than 94%, rather than 100%. Once alternative IV access is obtained, an IO line should be removed in order to prevent complications.

New recommendations recognize the probable benefits of vasoactive medications, including ionodilators such as inamrinone and milrinone, to treat postresuscitation myocardial depression. Further, dopamine may be useful for shock that is unresponsive to fluid, and norepinephrine for shock with low peripheral vascular resistance (septic, anaphylactic, spinal cord shock). Other agents include sodium nitroprusside, which increases cardiac output by decreasing the afterload, and dobutamine, which increases contractility and decreases peripheral vascular resistance (16). Norepinephrine and epinephrine are also commonly used inotropes.

Although current evidence is insufficient to recommend the routine use of systemic or selective cerebral hypothermia after resuscitation of children, it is important to avoid hyperthermia, especially in very low–weight infants. However, there are potential benefits of induced hypothermia (32 to 34˚C) for 12 to 24 hours following successful resuscitation, and critical care consultation should be obtained promptly (24).

Evidence suggests that the duration of resuscitation is not an adequate prognostic indicator of survival. Intact survival has been

reported even in cases with prolonged resuscitation and administration of epinephrine doses (25). Unfortunately, there are no reliable predictors of outcome to guide to the terminate resuscitation efforts. One should consider the mechanism of arrest, the duration of resuscitation, and the medications and doses that have been administered.

Common Pitfalls

- Failure to recognize age-appropriate vital signs
- Failure to maintain cervical spine precautions and recognize intra-abdominal or intrathoracic hemorrhage in cases of trauma
- Inadequate CPR with too few, too shallow, or too weak chest compressions, or frequent interruptions in CPR
- Inaccurate medication dosing and failure to use Broselow tape
- Failure to recognize sepsis early and provide early ventilation and support

CHAPTER 218

Pediatric Airway Management and Rapid-Sequence Intubation

Michele M. Nypaver

The ability to manage infants and children with respiratory distress is a fundamental skill required for emergency medicine (EM) and pediatric emergency medicine (PEM) practice. The conceptual framework of airway evaluation, action, and intervention summarized in previous chapters can be applied to children as well as adults. Hospital-based providers must be adept in the use of both temporary, noninvasive (NIV) airway adjuncts as well as intubation in the context of an infant or child with limited ability to communicate or cooperate. Variations in anatomy, size, morphology, and physiology encountered in young children add incremental complexity to the medical decision-making surrounding pediatric airway management. Despite the frequency of children visiting the emergency department (ED) with respiratory complaints, the need for intubation, even in high-volume pediatric emergency centers, is rare (1). However, infrequent exposure to children with severe respiratory illness represents a challenge for trainees who need this experience to establish initial proficiency and for emergency clinicians who must maintain competency in pediatric critical airway skills (2–4). Successful airway management in children demands a comprehensive approach to system readiness including planning, equipment availability, training, and regular practice to ensure optimal patient outcomes. High-fidelity simulation may play a role in

bridging the gap between the high stakes and low frequency of pediatric acute airway interventions. This chapter stresses the unique differences in the approach to airway management in children as compared to adults (see Chapter 1).

APPLIED ANATOMIC DIFFERENCES AND BASIC AIRWAY SUPPORT

Clinical presentations of respiratory distress in infants and young children are influenced by developmental stage. A rapid assessment of children using a brief visual approach based on a child's level of consciousness, breathing effort, and color is helpful to determine level of distress and initiate interventions (5). Careful interpretation of a child's response to people, surroundings, and examination is useful to guide the timing and level of intervention. Often, children in some distress but maintaining their own airway may be best served by *avoiding* interventions that increase anxiety and agitation which may precipitate decompensation, as in the case of suspected epiglottitis. The mnemonic "TICLS" is a quick bedside tool that has been validated for pediatric clinical assessment (6):

- Tone
- Interactiveness/Consolability
- Look/Gaze
- Speech/Cry

Clinicians should immediately intervene when infants or young children cannot be consoled or do not react appropriately to examination. Babies and toddlers typically cry or are fearful of strangers. Limpness, listlessness, or somnolence in a child should always prompt airway support and ongoing reevaluation of clinical status. Accurate measurement and monitoring of vital signs, including pulse oximetry, is required in every child in respiratory distress. Variation from normal values of vital signs by age should be recognized. Pediatric vital sign reference ranges should be immediately available to staff, particularly in settings where pediatric visits are infrequent.

Pediatric airway management requires recognition of differences in the anatomy and physiology of infants and children compared to

adults (**Tables 218.1** and **218.2**). The differences are most prominent during infancy and progressively become adult-like by approximately 8 years of age. With this in mind, clinicians can develop a systematic approach and anticipate the common challenges that arise during pediatric airway management. Infants and young children are prone to airway obstruction when the soft tissue mass of the tongue and tonsils fall posteriorly with supine positioning or relaxation induced by sedation or paralytic medications. Basic NIV airway support measures to relieve airway obstruction are easily applied, effective and are the foundation of pediatric airway management (8,9). Nontraumatized children demonstrating signs or symptoms of upper airway obstruction by anatomic structures (i.e., tongue and tonsils) who are awake may be less anxious when in a seated upright position. For those children who must remain supine, chin lift and jaw thrust can be used to relieve obstruction with or without a nasopharyngeal airway. Caution must be exercised during chin lift if an opposite hand is used to stabilize the forehead, in order to avoid neck hyperextension which may make obstruction worse. Positioning of young children is an underappreciated but basic and effective method to enhance airway patency. Raising the shoulders relative to the head using a towel or a cushion facilitates airway alignment, improves airflow during bag mask ventilation (BMV), and aligns the visual axes of the operator to the vocal cords (VC) during laryngoscopy. Various equipment sizes of suction tips, masks, and endotracheal tubes (ETTs) (in both larger and smaller sizes than anticipated) should be at the bedside to allow for rapid equipment choices when necessary. Other variations in airway anatomy encountered in children are those associated with congenital anomalies involving the head, face, and neck (Table 218.3). Presence of these conditions should immediately alert clinicians to the potential for a difficult airway.

TABLE 218.1
Anatomic Features of the Pediatric Airway, Clinical Impact, and Countermeasures

Feature	Clinical Impact	Countermeasure(s)
Larger soft tissue mass of tongue/tonsils in infants and young children	Airway obstruction when supine Difficult visualization of larynx/vocal cords (VCs) during laryngoscopy	No trauma: Chin lift, jaw thrust Trauma: Jaw thrust with in-line immobilization of C spine Use of straight laryngoscope blade (Miller) inserted to right side of mouth, sweeping tongue/soft tissue block to left Video laryngoscopy BVM with oropharyngeal (unconscious patient) or nasopharyngeal airway (conscious patient)
Large floppy epiglottis	Floppy epiglottis may partially block view to VCs	Use of straight laryngoscope blade places epiglottis "behind" the blade When using curved or straight blade, correct motion to lift tongue/soft tissues with operator thumb toward feet of patient
Higher positioning of larynx C1–4: Infants-children <7 yrs C4–5: Children >7 yrs to adult	Acute angulation causes difficulty in visualization of VCs during laryngoscopy may result in missed attempt or failure to intubate	Infants: Towel roll under shoulders Young children: Towel under head (sniffing position) Gentle cricoid pressure may be attempted but stopped if visualization is made more difficult "Hockey stick" bend of ETT to direct toward glottic opening Video laryngoscopy if available BVM
Conical shape of larynx compared to adult cylinder: Maximal narrowing subglottic below level of VCs	May be difficult to pass endotracheal tube (ETT) beyond VC Cricoid ring narrowed opening is larger in ant/postdiameter than lateral (elliptical)	ETT ready and available in sizes smaller than anticipated Uncuffed or cuffed tubes acceptable in children. If cuffed tube used, cuff pressure must be confirmed (American Heart Association 2010) Cuffed tubes *not* recommended for neonates (Neonatal Resuscitation Program 2010)
Small cricothyroid membrane size/diameter Infants: Mean 2.6 × 3 mm Adults: Mean 14 × 12 mm	Infants: Too small to accurately identify landmarks and carries laryngeal injury	For children in Can't intubate situations: Attempt BVM ventilation with/without oral airway or supraglottic device Surgical consultation

TABLE 218.2
Physiological Factors and Clinical Impact in Children Compared to Adults

Factor	Clinical Impact
Compliant chest wall	Inability to generate large negative intrathoracic pressure to inflate non compliant lung causes increased work of breathing
Immature musculature of intercostal muscles and diaphragm (less type I muscle fibers)	Limits ability of chest to fully expand Early chest wall fatigue Infants are dependent on functional diaphragms to ventilate
Smaller and narrowed airway causes increased airway resistance	Small changes in diameter of airway due to inflammation or edema cause large increases in airway resistance
Increased oxygen consumption	Infant oxygen consumption is up to twice (6 L/min) that of adults contributes to early/rapid hypoxia
Decreased functional residual capacity (FRC)	Compliant chest wall, small thorax, and large abdomen combine to reduce FRC in infants/young children. This is maximized during supine positioning Reduced FRC = diminished respiratory reserve = decreased time to desaturation during laryngoscopy

TABLE 218.3
Congenital Syndromes and Airway Anomalies

Name	Features
Pierre Robin sequence	Micrognathia (small mandible), glossoptosis, cleft palate
Goldenhar syndrome	Micrognathia (asymmetric), soft palate incomplete development
Treacher Collins syndrome	Micrognathia, small mouth, funnel shaped larynx
Apert syndrome	Midface anomalies, high arched palate, cervical fusion
Hunter/Hurler syndromes	Enlarged tongue due to mucopolysaccharides infiltration
Beckwith–Wiedemann syndrome	Macroglossia
Freeman–Sheldon syndrome	Fibrosis around mouth and microstomia

Emergency physicians must employ a proactive strategy to optimize oxygenation and ventilation early in all ill-appearing children to limit potential decompensation. Children become hypoxic

more quickly than adults because of greater oxygen consumption and a smaller functional residual capacity (FRC). Recognizing respiratory distress across a broad age range and disease spectrum in children is the first step in matching airway interventions to a specific patient at a specific point in their illness. Rapid changes in both respiratory and cardiovascular parameters in ill-appearing children should be anticipated. All children in respiratory distress should receive 100% FIO_2 titrated to pulse oximetry $>95\%$ delivered via the most effective means for a given clinical situation. Nasal cannulas may be used for children requiring minimal support; however any spontaneously breathing child in moderate to severe distress deserves 100% FIO_2 delivered via nonrebreather face mask. A child's clinical course and likelihood for deterioration may also be predicted in the context of age and disease. Young infants with bronchiolitis may present with subtle or mild respiratory symptoms followed suddenly by apnea. Asthmatic children may fatigue more quickly than older patients. Children with chronic lung, cardiac, and neuromuscular diseases may not follow a typical course in the setting of a superimposed respiratory illness given a more limited respiratory reserve. Convention dictates early airway support in children with respiratory distress in the setting of septic shock on the presumption of reducing overall metabolic demand; however there are very limited (and no pediatric) data analyzing the outcome of septic patients as a result of intubation or ventilation (8). While feeding children is an important comfort measure offered by caregivers of an ill child, caution should be exercised in offering food or drink to a child in respiratory distress to reduce potential for vomiting or aspiration should respiratory deterioration occur. Continuous cardiorespiratory monitoring including pulse oximetry is required in all children with difficulty breathing and especially for young infants, patients with chronic cardiac, neurologic or pulmonary conditions, children demonstrating evidence of shock, and those with anomalies that may heighten risk for airway compromise.

Patient size as a function of weight is vital for accurate airway equipment selection and medication calculations; a measured weight in kilograms is best but not always feasible to obtain. Tools and

formulas are available to reliably estimate weight in most circumstances when a child's condition precludes a measured weight (Table 218.4). The length-based color-coded Broselow tape is able to predict weight in children less than 10 years who are normal weight for length and weigh <25 kg; this tape has been validated in US pediatric populations and in other countries (10). Limitations of the Broselow and other length-based tapes include underestimation of weight compared to age-based formulas when children are at the extremes of weight for length, such as in preterm or malnourished infants as well as older and, more commonly, obese children. Age-based formulas to estimate weight are as accurate as the Broselow tape in weight prediction for children 25 to 40 kg. Arm circumference may predict weight more accurately than either age or height in children but evidence is limited and normative values are not readily available (11). The use of cognitive aids such as the Broselow tape to facilitate selection of equipment and drug dosing during airway and resuscitation emergencies is recommended by the American Heart Association Pediatric Advanced Life Support and American College of Emergency Physicians Advanced Pediatric Life Support authors (8). A summary of logistical issues in pediatric airway support is provided in Table 218.5.

TABLE 218.4
Weight/Size Estimation Tools and Formulas

Method	Benefits	Limitations
Length-based tapes (Broselow tape)	Accurate in children <10 yrs who are average height for weight up to 40 kg Recommended for use in all resuscitation/RSI calculations	Underestimate weight in obese and very young infants
Leffler formula, age Weight (kg) = (age in month/2) + 4 Children <1 yr Weight (kg) = (2 × age in years) + 10 Children 1–10 yrs	Accurate as length-based tapes in children 25–40 kg Better than length-based tapes for overweight children	Less accurate than length-based tapes for children <25 kg

NONINVASIVE AIRWAY SUPPORT

The advent of NIV airway interventions has extended the range of airway support beyond positioning, face mask oxygen, and endotracheal intubation. NIV airway interventions such as humidified high flow nasal cannula (HHFNC) and continuous positive airway pressure (CPAP) are increasingly being used in the care of some children in the ED setting. Although typically these had been reserved for infants and children in the intensive care unit (ICU), recent studies of children with bronchiolitis suggest that these NIV interventions may be valuable in the ED as a way to prevent

intubation (12,13). Data on outcomes such as need for escalation of support, frequency of intubation, and length of stay are still limited to retrospective reports and to prospective observational studies in select populations. There are as yet no randomized clinical trials in pediatric ED populations. Both HHFNC and CPAP require specialized equipment that is correctly sized for children and respiratory therapists and clinicians with clinical experience applying these techniques.

HHFNC is the delivery of humidified oxygen via a nasal cannula, using flow rates greater than the patient's peak inspiratory demand and delivered at temperatures typically between 35° to 37°C. Flow rates are not standardized; initial rates are usually 2 to 4 L/min, but can vary by weight and age up to 40 L/min. The mechanism of action is not completely understood, but may be related to increased airway distending pressure, more consistent flow of oxygen or washout of nasopharyngeal dead space.

NIV airway interventions have resulted in a significant reduction in the number of pediatric patients requiring intubation. Two small single-center pediatric emergency retrospective studies compared rates of intubation between time periods before and after HHFNC system introduction. In a heterogeneous population of ED children with acute respiratory insufficiency, an 8% reduction in intubation rate was noted largely by a reduction in ED intubations. Similar findings, a 7.6% reduction in ED intubations, were reported in patients started on HHFNC in the ED compared to children started on HHFNC in the PICU (18.1%) hours to days after admission (14). McKieranan et al. (12) retrospectively reviewed charts of children $<$24 months admitted to the PICU with bronchiolitis and compared rates of intubation before and after introduction of HHFNC, adjusting for age, weight, and RSV status. A dramatic 68% reduction in intubation during the postimplementation period was noted; however, these results must be interpreted with caution, as almost all patients (88%) received HHFNC in the postintervention period.

The addition of NIV methods requires vigilance on the part of practitioners to recognize when progression to endotracheal intubation may be required. A 2013 study assessed risk factors

associated with HHFNC failure in 498 children <2 years who received HHFNC within 24 hours of triage and included (1) initial venous pH <7.30, (2) triage respiratory rate greater than 90th percentile for age, and (3) PCO_2 >50 mmHg (15). HHFNC has demonstrated feasibility in children with bronchiolitis but has not been well studied in other pediatric ED disease populations. HHFNC may be a reasonable alternative in some children with bronchiolitis not requiring immediate intubation, in facilities where appropriate expertise and equipment are available.

A number of types of ventilation assist modalities are available beyond HHFNC, including CPAP, bi-level positive airway pressure (BiPAP), and nasal intermittent positive pressure ventilation (NIPPV). These methods all work by aerating atelectatic alveoli, increasing FRC, reducing respiratory workload, and improving oxygenation. Differences between these methods relate to the timing and control (patient versus machine) of gas delivery. CPAP delivers a constant flow of gas regardless of the patient's respiratory cycle while BiPAP delivers two distinct pressures delivered at fixed times or can be triggered by the patient's inspiration. NIPPV is essentially a hybrid of CPAP and BiPAP utilizing two flow meters delivering constant, but variable gas pressures; the machine is set to cycle between the two pressures at prescribed intervals (rather than being activated by the patient). The amount of oxygen delivered can be titrated separately or directly within each of the systems.

The most common pediatric emergency clinical application for CPAP is in the management of bronchiolitic children with acute respiratory distress who need more than simple oxygen yet do not require intubation. The major drawback of CPAP use in pediatric ED settings continues to be the requirement of a nasal or tight fitting face mask which may be difficult for an awake infant or young child to tolerate. Characteristics of children with bronchiolitis who require higher levels of airway intervention such as CPAP or intubation have recently been described in a PICU setting. Independent predictors of the need for CPAP/intubation were age <6 months, birth weight <7 lb, maternal smoking during pregnancy, onset of breathing difficulties <1 day before ED visit, presence of apnea, presences of

severe retractions, oxygen saturation <85%, and inadequate oral intake (13). The overall quality of evidence for CPAP use in children with respiratory distress in the ED setting remains very limited (17).

A summary of NIV (HHFNC, CPAP, and BiPAP) airway measures and their clinical application is shown in Table 218.6. The use of these techniques must take into consideration the ED setting, availability, experience of key personnel (i.e., physicians and respiratory therapists), and equipment resources. Complication rates are low, usually related to failure of the method to work (12–16). The method and timing of airway intervention depend on the clinical scenario, including disease process, existing comorbidities, age, and response to treatment. No randomized controlled trials have compared various NIV methods head to head in the ED setting and there are currently no guidelines or recommendations detailing use of these interventions. Decision-making for a child in severe respiratory distress rests with the judgment and experience of the emergency physician using the tools that he or she is most familiar with. NIV methods should not supplant or delay the use of BMV or intubation in any child whose clinical status progressively deteriorates. The ability to temporarily support oxygenation and ventilation through BMV has been shown to be as effective as endotracheal tube intubation (ETI) in children (albeit with increased risk of stomach insufflation and aspiration with prolonged use). In ED settings of care staffed by experienced providers, ETI should be performed in children with respiratory failure rather than subjecting them to prolonged BMV.

TABLE 218.6
Noninvasive Airway Support Methods

Method	Description	Clinical Application
High-flow oxygen (nasal cannula)	Heated and humidified high-flow oxygen delivered via nasal cannula Flow rates Neonates: 1–5 L/min Infants: 7 L/min Children: 7–8 L/min Adults: Max flow rate 50 L/min Flow rates and FIO_2 are titrated to desired oxygen saturation and work of breathing Nasal cannula sizes are chosen by fit; optimum fit allows some flow to escape (never fully occlude nares). Cannula fit directs size of equipment and maximum flow Patients require close monitoring for effect including heart rate, pulse oximetry, and capnography if available	Most evidence from children with bronchiolitis in PICU and some ED settings May reduce need for further escalation of airway support/intubation compared to standard nasal cannula O_2 in children with bronchiolitis Clinical effect should be seen within 60–90 min. Positive effect = decreased respiratory rate, work of breathing, accessory muscle use, and improved oxygenation No published guidelines for use in children in ED setting Requires respiratory therapy and experienced nursing staff
Continuous Positive Airway Pressure (CPAP)	Delivers constant positive airway pressure support Pressure range: Typical 5–10 cm H_2O Up to 15 cm H_2O Changes should be made in 1 cm H_2O steps Attached to oxygen blender Delivered by specific flow device or ventilator connected to flow device Requires delivery through nasal prongs (1 or 2 prongs), nasal mask, or oral nasal mask Patients require close monitoring for effect including heart rate, pulse oximetry, and capnography if available	Data from heterogeneous groups and settings (ED and PICU) bronchiolitis Contraindicated in patients with recent history of upper airway or GI surgery Requires respiratory therapy and experienced nursing staff No published guidelines for use in children in ED setting Patients need time for acclimatization Risk of air leak through prongs/nasal mask Face mask difficult to tolerate Effect should be seen 60–90 min
BiPAP/Bi-level nasal CPAP	Delivers two levels of positive airway pressure Higher pressure for inspiration 2–25 cm H_2O Lower pressure for expiration 2–20 cm H_2O Net pressure support = higher pressure – lower pressure Supplemental FIO_2 can be attached or blended within device Can be set to be triggered by patient breath or timed	Heterogenous population pneumonia, asthma, respiratory distress (ED and PICU) Contraindicated in patients with recent history of upper airway or GI surgery Requires respiratory therapy and experienced nursing staff No published guidelines for use in children in ED setting Risk of air leak through prongs/nasal mask Face mask difficult to tolerate Patients need time for acclimatization

RAPID-SEQUENCE INTUBATION

Rapid-sequence intubation (RSI) has been demonstrated to be both safe and effective in children (18). Inability to maintain or protect the airway, inadequate gas exchange (oxygen or ventilation), worsening clinical status, or potential for deterioration are the primary indications for RSI for children in emergency settings. Clinicians may also use RSI in other pediatric situations where ill or injured children may be unable to cooperate such as during prolonged transport or radiographic imaging procedures. Although no specific pediatric contraindications to RSI exist, clinicians should be aware of particular circumstances in children that signal a need for specific alternative airway plans. A quick algorithm for decision-making is available here (Fig. 218.1).

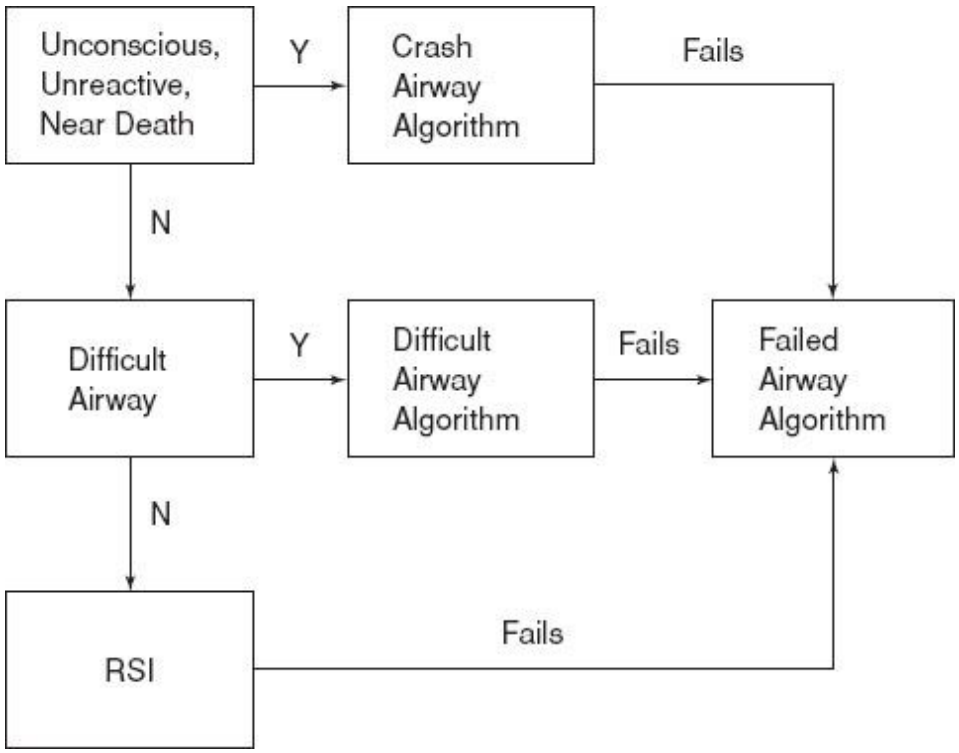

FIGURE 218.1 The universal emergency airway algorithm. (Adapted from Walls RM, Luten RC, Murphy M, et al. National Emergency Airway Management Course Manual. 3rd ed. Wellesley, MA: Airway Management Education Center, 1999.)

As in adults, RSI in children is a complex procedure requiring a mixture of cognitive and technical skill. First attempt success rates of EM physicians performing ETI during RSI of children are lower (53% to 77%) compared to adult RSIs and are positively correlated with operator experience (2,18,19). In a recent retrospective study from a busy children's hospital, ED EM residents' first-attempt success rate was 53% and attending level providers were 10 times more likely to be successful on the first ETI attempt compared to all trainees combined (2). More concerning, in the same study of 114 videotaped RSI procedures, were higher overall rates (including attending physicians and trainees) of first-attempt ETI failure (52%) and adverse effects (61%) compared to previous reports; adverse effects were also not reliably captured in written documentation. As with any infrequently utilized critical skill, pediatric RSI requires advance preparation as well as integration with system improvement

planning; this includes attention to training, maintenance of skill, and ongoing event monitoring to ensure safe practice for optimal patient outcomes. The Advanced Pediatric Life Support and Pediatric Advanced Life Support courses include chapters and skill stations on RSI. Mock codes and practice sessions are invaluable to multidisciplinary team members.

The seven "P's" are a useful cognitive aid to recall the series of actions required to perform RSI. With an emphasis on preparation to avoid complications and mitigate potential aspiration from a full stomach the mnemonic is applicable to both adults and children. The steps of RSI are as follows:

1. Preparation
2. Preoxygenation
3. Premedication
4. Induction and paralysis
5. Cricoid pressure
6. Intubation
7. Postintubation management

Figure 218.2 presents a timed flowchart of the procedure. **Tables 218.7** to **218.10** outline the medications, dosing, and clinical situations that direct used in the scheme.

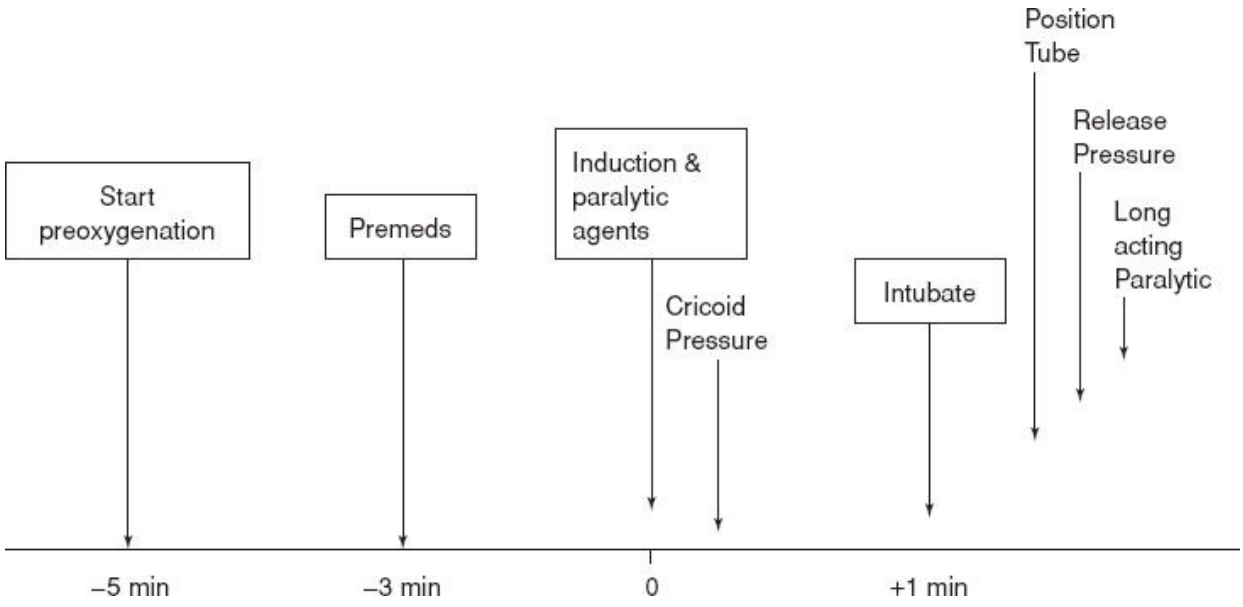

FIGURE 218.2 Rapid-sequence intubation. This chart reflects details of the timed sequence of the procedure in the stable patient. It is important to note that all time intervals may be abbreviated by the clinician, when deemed necessary, owing to less than optimal or deteriorating clinical status.

TABLE 218.7
Common Premedications in Rapid-Sequence Intubation

Drug	Dose (IV)	Action
Lidocaine	1.5 mg/kg	Lowers ICP
Atropine	0.02 mg/kg	May consider to prevent or correct bradycardia associated with airway manipulation and succinylcholine
Pancuronium/vecuronium (defasciculating dose) Defasciculating dose is not recommended for children	0.02 mg/kg	Prevents fasciculations and ICP elevations from succinylcholine (may consider in teenagers and adults)
Fentanyl (optional and usually not recommended in children)	1–5 µg/kg	Attenuates sympathetic discharge and resultant elevations in ICP. Use with caution. May cause respiratory depression or blunt compensatory sympathetic tone

ICP, intracranial pressure.

TABLE 218.8
Suggested Induction Agents for Specific Clinical Conditions

General Sequence	Etomidate, Propofol, Thiopental, Midazolam, Ketamine	Provider Preference
Poor perfusion	Ketamine	Propofol, thiopental, midazolam are more prone to cause hypotension. In the presence of potential septic shock etomidate should not be used due to interference with steroid production.
Elevated ICP	Etomidate, propofol, thiopental, midazolam, consider ketamine	Traditionally ketamine has not been recommended in conditions associated with elevated ICP because of the potential to further exacerbate cerebral pressure levels. Recent evidence, however, suggests a beneficial effect of the drug in these patients. Benefits may be mediated through favorable effects on cerebral perfusion and by conferring protection against humoral mediators of neuronal cell death. The data demonstrating this effect come from the adult literature. Most sources do not recommend ketamine for this indication in children yet and still maintain the cautionary stance to its use in patients with potential ICP elevation
Asthma/ RAD	Ketamine etomidate propofol, midazolam	Thiopental may cause histamine release with resultant bronchospasm
Hyperkalemia risk	Propofol, etomidate, thiopental, midazolam ketamine	

ICP, intracranial pressure.

TABLE 218.9
Common Agents for Induction of Unconsciousness in RSI

Drug	Dose (IV)	Onset	Duration
Thiopental	3–5 mg/kg	10–30 sec	10–30 min
Ketamine	1–2 mg/kg	1–2 min	15–30 min
Midazolam	0.2 mg/kg (maximum 5 mg)	1–2 min	30–60 min
Etomidate	0.2–0.4 mg/kg	1 min	3–14 min
Propofol	1.0–2.0 mg/kg	30–60 sec	10–15 min

RSI, rapid-sequence intubation.

TABLE 218.10
Common Agents for Muscle Relaxation in RSI

Drug	Dose (IV)	Onset	Duration
Succinylcholine	1.0–1.5 mg/kg (>10 kg) 1.5–2.0 mg/kg (<10 kg)	30–60 sec	4–10 min
Vecuronium	0.2–0.25 mg/kg (RSI)	60–90 sec	90 min
	0.1 mg/kg (standard dose)	2–3 min	25–40 min
	0.01 mg/kg (defasciculating dose)		
Pancuronium	0.1 mg/kg	2–5 min	45–90 min
	0.01 mg/kg (defasciculating dose)		
Rocuronium	1.0–1.2 mg/kg	30–60 sec	25–60 min

PREPARATION

Preparation for RSI begins with assessment of the child's airway with consideration of the clinical scenario and level of difficulty anticipated. All patients require a basic and contingency RSI plan for failed or unexpected difficult intubation. Histories of prior difficult intubation or expected difficult intubation are critical to contingency planning. Advanced airway supplies in pediatric sizes should be immediately available (and checked at regular intervals) for use in difficult intubation situations such as a videolaryngoscope, lighted stylets, bougies, laryngeal mask airways (LMA), combitube, and surgical trays with materials to facilitate a crash surgical airway. These plans should also integrate larger system protocols to escalate help through alerts to additional advanced personnel (such as anesthesiology) and include procedures for moving a child to the

operating room if necessary. A directed assessment of the airway before RSI and common assessment tools such as the Mallampati score or LEMON evaluation can be applied to children; however data to support their use is limited. History and clinical scenario alone can, typically, direct attention to the likelihood of encountering problems. Extreme caution should be exercised before sedation or paralytic medications are given to any infant or child with craniofacial problems (including injury) that may impede bag-valve-mask (BVM) ventilation; these children may benefit from use of reversible medications with backup support in attendance during RSI or consider moving the patient to the operating room for the procedure.

Equipment required for RSI in children is summarized in Table 218.11; all equipment should be checked prior to the procedure. Both curved (e.g., Macintosh) and straight (e.g., Miller) laryngoscope blades with handles should be available for clinician flexibility particularly when intubating infants and young children <2 years. Choice of curved versus straight blades remains at the discretion and experience of the clinician. Curved blades are often used in children older than 2 years (Figs. 218.3 and 218.4). However, the Miller 2 blade is a reliable blade in children between the ages of 2 and 10. It may be used as a traditional straight blade that lifts the epiglottis or as a curved blade placed in the vallecula.

TABLE 218.11
Equipment Required for Rapid-Sequence Induction

Oxygen source
Bag-valve masks
Face masks (100% nonrebreather)
Oral and nasopharyngeal airways
Laryngoscope handles
Laryngoscope blades
Suction system
Endotracheal tubes: Cuffed and uncuffed
Stylet
Cardiac monitor
Pulse oximeter
Difficult airway cart: Laryngealmask airway (LMA), videolaryngoscope, tracheal tube devices (lighted stylet, ventilated stylet), Bougie
Needle cricothyroidotomy supplies
End-tidal CO_2 detector

endotracheal intubation. In: King C, Henretig FM, eds. *Textbook of Pediatric Emergency Procedures.* 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2008, p168. Copyright © 2008. Lippincott Williams & Wilkins.)

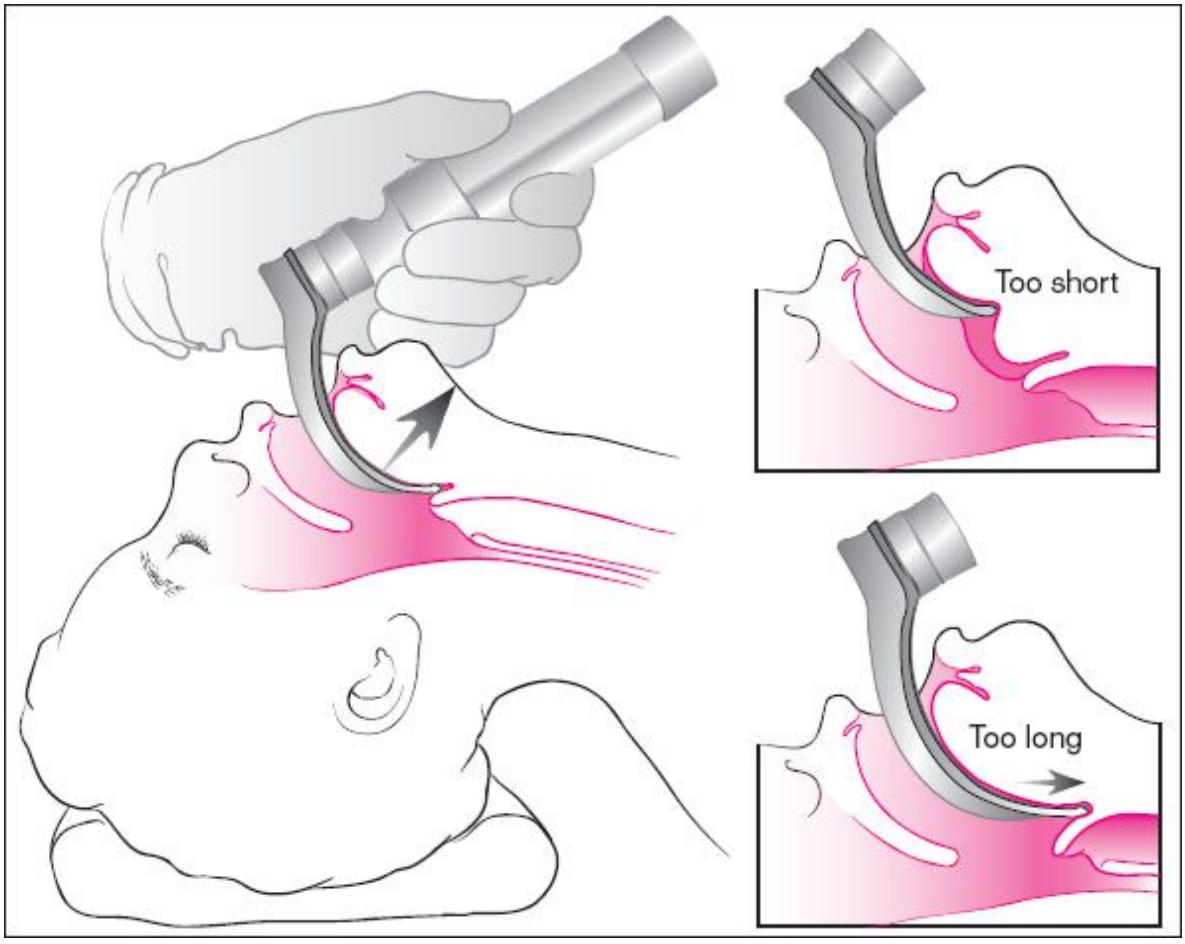

FIGURE 218.4 Direct laryngoscopy using a curved blade. (Reproduced with permission from King C, Rappaport LD. Emergent endotracheal intubation. In: King C, Henretig FM, eds. *Textbook of Pediatric Emergency Procedures.* 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2008, p170. Copyright © 2008. Lippincott Williams & Wilkins.)

Previous RSI instruction directed operators to avoid cuffed ETTs in children under 8 years. However, recent evidence has found cuffed ETTs to be safe and effective in young children and infants. New low-

pressure, high-volume cuffed ETTs have not been associated with tracheal injury or long-term complications (20,21).

Length-based tapes (e.g., Broselow) reasonably predict ETT size selection in most situations, but may not provide guidance for children requiring smaller cuffed tubes (e.g., < 5.5 mm). Suggested formulas for sizing cuffed ETT in young children are listed in Table 218.12 (8). A general rule that may be applied in these situations is to choose the cuffed tube 0.5 to 1 size smaller than the estimated size of an uncuffed ETT. Cuffed tubes may be preferable in situations where children are at risk for aspiration and those requiring potentially higher ventilator pressure settings (such as bronchiolitis or asthma) (8,21). Small stylets are available for infant sized ETT; however, the largest stylet available should be utilized ensuring it does not protrude beyond the end of the tube.

TABLE 218.12
Calculations for Cuffed ETT Sizing in Young Children

Age	Size
Less than 1 yr (>3.5 kg)	ID = 3.0 mm
1–2 yrs	ID = 3.5 mm
Greater than 2 yrs	ID (mm) = Age in years/4 + 3.5

ID, internal diameter.

Cervical spine collars in children with suspected injury restrict laryngoscopy. Opening the collar anteriorly with in-line immobilization to prevent movement of a potential cervical spine injury may facilitate placement of the ETT; however this procedure may still offer incomplete view of the glottis, may not arrest all cervical spine movement, and can result in higher force generated during visualization of the cords (22,23). Operators will need to balance the force generated during laryngoscopy with existing in-line stabilization maneuvers to allow adequate visualization while minimizing cervical spine movement to the greatest degree possible.

Preoxygenation

Two to three minutes of preoxygenation are required in spontaneously breathing children or 1 to 2 minutes of BMV with 100% FIO_2 in an apneic child to allow a "safe" period of apnea by establishing a physiologic oxygen reservoir for laryngoscopy without desaturation. Practitioners should supply the highest level of oxygen to the patient as soon as RSI is contemplated. Patients with respiratory insufficiency or impending failure will be challenging to preoxygenate and may require BMV using small tidal volumes to minimize gastric insufflation and hence the risk of subsequent vomiting and aspiration. Deflation of the stomach with a nasogastric tube is indicated if gastric distention, despite an increased risk of vomiting and aspiration, impedes oxygenation or the effectiveness of BMV before ETI. Chronically ill children with gastrostomy tubes in place can be vented to accomplish the same goal.

Premedications

Premedications, including atropine, lidocaine, and defasciculating doses of neuromuscular blocking agents, may be considered to blunt physiologic responses to laryngoscopy or neuromuscular blockade; however, evidence for the use of the agents listed above is either clinically ineffective or controversial due to limited evidence (Table 218.7).

Atropine has traditionally been administered in pediatric RSI to control reflex vagal stimulation and bradycardia related to laryngoscopy and the use of succinylcholine. These phenomena allegedly occur most often in children under 1 year of age and are attributed to a relative predominance of vagal tone in the immature neonatal ventricle. This predisposes the heart to wider pulse rate variations under stress whose effects are potentially mediated and/or blunted by atropine. This relative parasympathetic/sympathetic imbalance recedes by approximately 6 months of age making the indications for atropine beyond the first year of life less clear. There is no conclusive evidence to either support or refute the use of atropine pretreatment; however, recent evidence suggests a trend away from the routine use of atropine in pediatric RSI across many

specialties including anesthesia and neonatology (Rothrock). In addition, while the AHA, ACEP and the AAP have maintained guidelines for the use of atropine in the following populations: (1) *all* children under 1 year undergoing RSI, (2) children less than 5 years in whom succinylcholine is used as the paralytic agent, and (3) in any child requiring a second dose of succinylcholine during RSI (25). *none of these organizations dictate atropine pretreatment as the standard of care in pediatric RSI* (Rothrock). *Atropine has a number of significant side effects to be considered in the context of the ED patient. These include paradoxical bradycardia if less than the minimum 0.1 mg dose is given, urinary retention, reduction of lower esophageal sphincter pressure, pupillary dilatation, and tachycardia that may last hours beyond the procedure.* These effects could make assessment of head injured patients more challenging and make hypoxemia that presents with bradycardia more difficult to detect. Given the paucity of evidence, no conclusions can be drawn regarding the use of atropine for pretreatment in pediatric RSI. It *may* be useful for infants less than 1 year of age but is not routinely recommended beyond this age.

Lidocaine has a long history in RSI algorithms of adults and children to mitigate the transient increased intracranial pressure (ICP) associated with laryngoscopy and intubation. However, as in adults, its use in the pediatric population is rightly questioned (24).

Defasciculating agents of neuromuscular blocking drugs are not recommended in children. The transient increase in ICP induced by succinylcholine is not considered clinically significant enough to warrant the addition of supplemental agents to the RSI protocol (25).

In conclusion there is no evidence to support premedication of the pediatric RSI patient. Simplicity should be valued over potential of medication errors, side effects, or unclear significance of the treatment.

INDUCTION WITH PARALYSIS

Choice of sedation and neuromuscular blocking agents in children depends largely on the clinical situation and hemodynamic status of the patient (Table 218.8). Controversy exists regarding the optimal sedative in pediatric RSI and no perfect agent exists. Ketamine and

etomidate are the commonly used and well-studied sedatives in RSI algorithms of adults and children. Etomidate is a frequently used and well-studied agent in pediatric RSI. It is a rapid and effective sedative with minimal negative hemodynamic effects and has neuroprotective properties (decreases cerebral metabolic rate and blunts ICP). Its impairment of endogenous corticosteroid synthesis, even after a single dose, is a drawback particularly in septic patients. As a result current recommendations from the American College of Critical Care Medicine and the American Heart Association discourage use of etomidate in the setting of suspected sepsis (8).

Ketamine, a widely used dissociative pediatric deep sedation agent, is also a reasonable choice of sedative for pediatric RSI, given its reliable sedative profile and its positive effects on heart rate and blood pressure. However, a recent report of cardiovascular collapse in two separate cases following a single dose of ketamine during RSI have raised concern (26). The majority of children following ketamine administration experience positive chronotropic cardiac effects and an increased blood pressure secondary to the sympathomimetic catecholamine release, overriding ketamine's lesser direct negative inotropic effects. Thus, the usual hemodynamic protective qualities seen with ketamine depend upon adequate catecholamine stores to balance its negative effects. Patients with depleted catecholamine stores (due to the stress of chronic or critical illness) may be at risk of negative hemodynamic effects such as sudden hypotension and bradycardia.

Clinicians must appreciate the pharmacology of sedative agents in the context of patient characteristics and the clinical situation at hand to choose the safest, most reliable option for sedation and induction. Ketamine is the preferred sedative agent in the child with presumed sepsis unless further evidence emerges to the contrary. Consideration should be given to use of other sedatives in patients with suspected catecholamine deficiency in whom ketamine is being considered.

Other sedatives include midazolam, thiopental, and propofol. While these agents offer value in RSI for their induction properties, either respiratory or myocardial depression or both may limit use in

children, especially for those presenting with hemodynamic compromise prior to RSI. Midazolam may be employed in adult and pediatric RSI but sedation can be unreliable (27). Thiopental is a short-acting barbiturate with neuroprotective characteristics that serves as a first-line induction agent in many institutions but has largely been supplanted by newer agents. Thiopental reduces cerebral oxygen consumption but may also cause vasodilatation, myocardial depression, and hypotension, as well as histamine release. This limits its use in children with hemodynamic instability or asthma. Similarly, propofol offers excellent intubating conditions, but with a trade-off of hypotension and potential hypersensitivity reactions in children with unrecognized egg or soybean allergy.

Paralytic Agents

Depolarizing and nondepolarizing paralytic agents are used to enable laryngoscopy and ETI via general muscle relaxation. Succinylcholine is a commonly used paralytic in adult as well as pediatric RSI; given in doses higher than adults it is attractive for its rapid onset and resolution of symptoms. Succynlcholine does have significant drawbacks including rare instances of bradycardia and even asystole in children. Additionally, hyperkalemia is known to occur immediately as well as in a delayed fashion in children with known or suspected neuromuscular diseases (including burns, muscle injury or atrophy, motor neuron lesions, muscular dystrophies) resulting in cardiac arrest. Of particular importance are the known contraindications to succinylcholine applicable to children including any child with a history of or potential for hyperkalemia, malignant hyperthermia, known injury with crush, burn, or denervation within the last 48 to 72 hours, preexisting denervating neuromuscular disease, or suspected myopathy. Nondepolarizing agents including vecuronium, pancuronium, atracurium, and shorter acting agent rocuronium are frequently used in children but are typically slower in onset and last longer than succinylcholine (Table 218.10). Of these, rocuronium offers the best features most closely resembling succinylcholine in time of onset. In many institutions rocuronium is the first-line agent in children. The RSI team should be prepared for

rapid changes in vital signs and clinical status at all points during the procedure and ensure reliable vascular access with ability to rapidly deliver fluids and/or pressor support when necessary. As in adult patients ongoing sedation and paralysis should be maintained with appropriate agents such as midazolam and vecuronium.

CRICOID PRESSURE

The Sellick maneuver, consisting of digital cricoid pressure to occlude the esophagus and prevent passive regurgitation, has been advocated as part of the required sequence for RSI. Routine use of cricoid pressure has not been shown to prevent aspiration reliably and may interfere with laryngoscopic viewing of the glottic opening (8). Recent evidence based on CT imaging of the neck in children suggest variation in the anatomic position of the esophagus relative to the trachea, noting that the esophagus does not always lie directly behind the cricoid cartilage (28). It is thus reasonable to consider using cricoid pressure initially during pediatric RSI until the ETT is placed or the laryngoscopist requests removal to optimize the view of the VC.

Endotracheal Tube Placement with Confirmation

As in adults, it is vital to confirm tube placement in the trachea. Colorimetric CO_2 detection devices (confirming change from purple to yellow) are very reliable and widely used. Correctly intubated hypotensive patients with poor perfusion may not display a clear color change due to limited exhaled CO_2. In these cases a second laryngoscopy with the tube in place may be performed to confirm proper placement. Auscultation of breath sounds, chest rise, and radiographic confirmation of the ETT in the correct position are important secondary adjuncts to confirm tube placement.

RESCUE TECHNIQUES

Proper patient positioning, aggressive preoxygenation, use of appropriate oral and nasal airway adjuncts, and good BMV technique are the best methods to avoid a failed airway in both children and

adults. For children, the most readily available backup airway technique for the patient who cannot be bagged is placement of an LMA (7,8). LMA placement in children is essentially the same as in adults; however, the larger pediatric epiglottis may fold back into the airway as the LMA is placed, causing obstruction above the glottic opening and resulting in an inefficient seal. Both of these problems can usually be corrected quickly by withdrawing of the tip of the LMA slightly to allow either the epiglottis or the LMA tip to unfold and then reseating the tip.

Specific recommendations for management of the difficult pediatric airway beyond LMA are challenging. Video laryngoscopy is a rapidly emerging technology in pediatric EM and has an established track record in adult EM (see Chapters 1 and 2). Pediatric experience is evolving and pediatric sized laryngoscope attachments are available. Trainees and novice operators were successful in placement of ETTs in a mannequin after brief instruction on the use of videolaryngoscopy (29,30). Nonetheless, no official guidelines for the use of videolaryngoscopy in the difficult pediatric airway are available. More than ever, individual providers must familiarize themselves, practice, and demonstrate proficiency in airway tools available to them in their practice setting.

Needle cricothyrotomy is rarely performed in the pediatric population, but the technical placement of the catheter is very similar to the cannulation of a vein. Although various percutaneous needle cricothyrotomy kits and needles are commercially available, the simplest equipment that is appropriate for use in infants consists of a 14-gauge over-the-needle catheter, a 3.0-mm ETT adapter, and a 3- or 5-mL syringe (31). The trachea is isolated, and the 14-gauge angiocath attached to the syringe is inserted directly inferior to the thyroid cartilage at an angle of approximately 30 degrees. The cricothyroid membrane cannot be palpated in the child, so the catheter is placed through the tracheal rings. Any damage to the tracheal cartilage that may occur during needle insertion can be repaired at a later time. Air is aspirated as the catheter is inserted to ensure proper placement. The catheter is left in as the needle is gently withdrawn. The catheter is then attached to the 3-mm ETT

adapter to which a high-pressure source of oxygen can be attached. The provider should expect significant resistance as the patient is ventilated through the catheter, although some definite airflow with chest rise should occur. Needle cricothyrotomy is a rescue modality to gain time until a definitive airway is established. While oxygenation may be preserved, ventilation is likely to be inadequate and progressive hypercarbia is to be anticipated.

CRITICAL INTERVENTIONS

- Select premedications and sedative and paralytic agents taking into consideration the patient's history, age, and physiologic status.
- Have a plan in place for management of the failed airway that includes a minimum of BMV, LMA, and needle cricothyrotomy.
- Have a quality improvement system in place for pediatric RSI that includes all clinicians, nursing, and technical personnel, and addresses medications, equipment, RSI, and failed airway protocols, as well as provision for simulation education with regularly scheduled training exercises.

Common Pitfalls

- Failure to preoxygenate.
- Failure to obtain an adequate laryngoscopic view due to incorrect size or use of equipment.
- Failure to follow succinylcholine with intravenous sedation and a nondepolarizing agent in patients requiring prolonged mechanical ventilation.
- Failure to verify ETT position both clinically and with an end-tidal CO_2 detector.
- Failure to prepare for unanticipated difficult pediatric airway situations during each RSI.

CHAPTER 219

Vascular Access in Children

Matt Hansen

Children are a heterogeneous group in regard to vascular access, with unique needs in different age groups. Besides the size and depth of the vessel to be cannulated, challenges include control of the patient's physical motion, while pain, anxiety, and parental concerns are addressed. This chapter reviews peripheral venous access, central venous access, ultrasound-guided access, and intraosseous access in children, and discusses techniques for anxiolysis and analgesia during these procedures.

PERIPHERAL VENOUS ACCESS

Peripheral venous access is a cornerstone of modern medical care. Veins in children are often of small caliber requiring narrow-gauge IV catheters. The skin can be thin, and vessels are often more superficial than in adults. Furthermore, the pain and anxiety associated with peripheral access in children is significant (1). Besides even in neonates, neural pain pathways are well developed and it is believed that pain can condition the patient's future responses to painful events. In this context, it is ideal to obtain access as quickly and efficiently as possible, minimizing the number of IV attempts and the resulting stress to the patient and family. Placing a peripheral IV catheter in children requires more nursing resources, may take longer than in adults, and often requires active management of the patient's position and anxiety by a second

operator. Providers must consider the utility of the catheter and whether there are alternative options. For example, an IV catheter is often placed to check electrolytes and infuse fluid bolus in a child with dehydration from gastroenteritis. However, other than a bedside glucose, laboratory testing is of little utility in this situation, and oral rehydration is equally as effective as IV hydration in most circumstances.

The anatomic locations best suited for peripheral access in children are similar to those in adults, but with a few notable exceptions. First, the saphenous vein is a relatively large vein with a consistent location and can be accessed blindly using anatomic landmarks. It can often be located 1 to 2 cm superior and 1 cm medial to the medial malleolus, and then runs posteriorly toward the popliteal fossa. Use of a tourniquet and careful palpation may assist in locating the vessel. The antecubital fossa is another site which is relatively easy to cannulate in children, but it may be difficult to secure and maintain a line due to inadvertent kinking as a result of elbow flexion.

Several techniques may improve the success in difficult IV access in children. Placing a tourniquet on the extremity may also increase the caliber of the vessel and improve the likelihood of success. Transillumination of the hand or foot is a technique which can improve visualization of veins in these locations. A cool light source is needed in order to avoid damage to the skin. Several types of light source are available, including fiberoptic sources.

ULTRASOUND-GUIDED PERIPHERAL ACCESS

Ultrasound-guided peripheral access is another option in children. Ultrasound has been shown to be more accurate than external landmarks in localizing the saphenous vein in children and has been used to insert IV catheters in infants (2,3). In addition, ultrasound has been shown to reduce the time and number of attempts required in children with difficult access (4,5). However, the experience level of the sonographer 1 is an important factor in actual use 6. The technique for obtaining ultrasound-guided peripheral access in

children are similar to those in adults and are well described (7,8). However, in small children or neonates, in whom some veins may be too close to the ultrasound probe to appropriately visualize, a stepoff pad or small bag of saline may be placed between the probe and patient to provide more distance between the probe and the target vein.

CENTRAL VENOUS ACCESS

Central venous access is rarely required in children in the emergency department (ED), largely because of the advent of powered intraosseous devices (discussed below). However, there are times where pediatric central access may be needed. The common locations for pediatric central access include the femoral vein, internal jugular vein, and subclavian vein, and the anatomic landmarks for obtaining central access in children are similar to those in adults. Complications of central access in children are similar to those in adults as well, though because of the relative proximity of important anatomic structures in children, increased vigilance is needed to avoid serious complications. Furthermore, it is frequently impossible to safely obtain central access in young children and infants who are awake or nonintubated, and in whom movement cannot be otherwise controlled.

The femoral vein is often felt to be the technically easiest location for inserting a central venous catheter and has the advantage of being distant from the heart, lungs, and carotid artery. Femoral lines are often avoided in adults because line infections are more common than with internal jugular and subclavian lines, though this is not necessarily the case in children (9).

One notable circumstance where a femoral line is relatively contraindicated is in diabetic ketoacidosis (DKA), where there is a strong association between femoral vein central line placement and subsequent deep vein thrombosis (9). Intraosseous access is the route of choice in patients with DKA in whom peripheral access cannot be established.

The use of ultrasound for central access has become routine in adults. There is evidence that, as in adults, the use of ultrasound for central access in children also lowers complication rates and improves success rates for both internal jugular and femoral sites (10–13).

INTRAOSSEOUS ACCESS

The intraosseous route provides access to a noncollapsible structure with reliable landmarks and relatively few associated contraindications. Powered intraosseous access has dramatically changed emergency access in critically ill children. Several devices are currently available, the most commonly used in the United States is the EZ-IO. Powered intraosseous access is rapidly obtained (typically in less than 1 minute) and complications are rare. The procedure can be easily learned on models or manikins by a wide variety of practitioners, from paramedic to physician (13,14). The IO has had high success rates in patients of all ages, including neonates, and has the potential to replace umbilical vein access in the ED (15). The most common location for intraosseous access is the proximal tibia, though access at the humeral head, distal femur, and distal tibia are also well described. Sternal osseous access has mostly been used in the military setting.

Proximal tibia placement via the EZ-IO will be described since the EZ-IO is the most frequently used device in the US and the proximal tibia the most common site for placement. In order to avoid the physis, the site on the proximal tibia to be accessed is approximately 2 cm distal to the tibial tuberosity. The needle is placed on the skin perpendicular to the bone. The trigger is depressed and remains engaged until the needle has been passed through the cortex of the bone. The operator should feel a sudden reduction in the pressure required to advance the needle once the needle is through the cortex. Care must be taken to not drill in an oblique manner or to go too deep as the needle could pass through the posterior cortex. After the needle is in place, the stylette is removed from the needle and an IV connector is attached. Placement can be confirmed by

aspiration of bone marrow; however, the needle can be in good position and marrow not aspirated. In this situation, the catheter is flushed while palpating the area around the needle and posterior to the needle to monitor for extravasation. If the line flushes easily it is presumed to be in good position. One must be vigilant during the use of an IO for extravasation. This is the most common complication, and can occur posteriorly or lateral to the site of placement, depending on the angle and depth of the needle. The IO needle can be secured by bolstering with gauze and tape, using tape alone, using commercially available products, or other means. Regardless of the method used, it is important to be able to visualize the area near the hub of the needle and posteriorly.

Anything, including fluids and medications, that is administered by an IV can be given through an IO. Fluids infused by the IO route rapidly reach the central circulation. Although IO needles have a large bore, the medullary cavity of the bone has a somewhat high resistance, and IV pumps or pressure bags are frequently needed to aid in rapid fluid administration. In addition, rapid infusion of fluids into the medullary space can be painful, so lidocaine is often administered (0.5 mg/kg via slow push) prior to rapid fluid boluses. In general, longer use of IO access is likely to lead to more complications; thus, IO access is a temporizing means of access until a more stable route can be established.

Contraindications to IO access include infection at the site of insertion, fracture proximal to the site of insertion, suspicion of compartment syndrome in the extremity, previous IO attempt, or bone abnormalities raising the risk of fracture such as osteogenesis imperfecta. Complications include extravasation, skin necrosis, compartment syndrome, cellulitis, osteomyelitis, air embolism, and fracture (16–21). Most are directly related to extravasation of substances which can cause tissue necrosis due to misplacement or dislodgement of the needle, not due to anything inherent in the IO itself. This reinforces the need for vigilance at the site of placement.

ANALGESIA AND ANXIOLYSIS

Analgesia and anxiolysis for vascular access in children can be improved by using both behavioral and pharmacologic techniques. Behavioral techniques start before the procedure and involve providing information on the procedure in a developmentally appropriate manner. Both patients and parents can be taught coping techniques such as deep breathing. Parents can assist in providing a position of comfort and can be actively engaged in distraction, which can be an extremely powerful tool in mitigating anxiety related to a procedure. For infants, comfort may be improved by swaddling, skin to skin contact, breastfeeding, and sucrose administration. Following the procedure, encouragement and distraction are helpful to further reduce anxiety and anticipation of future events (22).

Pharmacologic techniques for analgesia and anxiolysis are myriad (1). Pharmacologic anxiolysis for IV starts may be achieved by inhaled nitrous oxide, or by midazolam, which can be administered via the intranasal, oral, or buccal routes. Pharmacologic analgesia can be achieved by local infiltration, transdermal creams, and active delivery mechanisms. Local infiltration of lidocaine is less painful than IV cannulation, but does involve a needle stick, and perhaps for this reason is not widely used. The J-Tip (National Medical Products Inc., Irvine, CA) is another option for local infiltration and uses CO_2 to inject lidocaine. Several studies demonstrate that it has rapid onset and is effective, though it was associated with a reduced rate of successful cannulation in one adult study. Lidocaine and prilocaine cream 2.5%/2.5% has been shown to be effective in multiple studies at reducing the pain associated with venipuncture. The time needed for this to be optimally effective is 60 minutes, though 90 minutes is more effective. This product is not intended for use on broken skin, as it may result in systemic absorption. Tetracaine gel, not available in the United States, is also effective and requires less time to achieve its effect than the lidocaine and prilocaine mixture. Liposomal 4% lidocaine has also been shown to reduce pain in children when starting a peripheral IV, but as with similar agents, needs 30–60 minutes to achieve its desired effect.

Complications are few and generally involve local skin irritation. Many other techniques have been described to facilitate delivery of local anesthetics through the skin, including heat and lasers. Finally, vapocoolant sprays have been used as analgesics and act by causing temporary (less than 1 minute) cooling of the skin in the area. Studies evaluating efficacy have been mixed, however, probably due to the extremely short duration of action, which may be insufficient for starting an IV.

CHAPTER 220

Procedural Sedation, Anxiolysis, and Analgesia

Raymond D. Pitetti

Children often require relief of pain and anxiety when undergoing diagnostic or therapeutic procedures in the emergency department (ED). Despite adequate local anesthesia, distraction techniques, and reassurance, many children are unable to "lie still" during a procedure without being physically restrained. Physically restraining a child may facilitate the successful completion of a procedure but can result in psychological trauma for the child and creates less than optimal procedural conditions for clinicians. As a result, procedural sedation and analgesia (PSA) has become standard practice in the outpatient setting to help optimize care of such patients.

Historically, physicians have done a poor job of alleviating pain and anxiety in children undergoing diagnostic testing and procedures (1,2). Even as recently as 20 years ago, it was a commonly held belief among healthcare professionals that young children undergoing a painful or anxiety-provoking procedure did not experience pain, would be at risk of becoming addicted to opiates if they were used, would retain no memory of the event, and would not experience any lasting effects. Dramatic advances in procedural sedation techniques, a greater understanding of the pharmacodynamics of available sedatives and analgesics, and a greater understanding of the physiology and behavioral aspects of how children experience pain have led to an increase in the use of

procedural sedation and to improved safety practices governing its use.

Providing effective and safe ED PSA requires a well-defined process including (1) preprocedural patient assessment; (2) appropriate selection of pharmacologic agents; (3) careful intraprocedural monitoring; and (4) proper postprocedure evaluation and discharge. In addition, complete and thorough documentation of each aspect of the sedation process should be included in the medical record, since many aspects of the sedation process are important JCAHO requirements.

GUIDELINES FOR PEDIATRIC SEDATION AND ANALGESIA

Guidelines for pediatric PSA (3) were first developed and published in 1985 by the National Institutes of Health and the American Academy of Pediatrics (AAP). These guidelines described patient selection, monitoring, equipment needs, and attempted to define various levels of sedation and analgesia. In 1996, the American Society of Anesthesiology (ASA) Task Force on Sedation and Analgesia by Non-anesthesiologists published similar guidelines. These guidelines sought to bring together consensus opinions proposed by various subspecialty societies (4). A recent revision by the ASA in 2002 and by the AAP in 2006 defined the various states of sedation as follows:

Minimal sedation: Drug-induced state during which patients respond normally to verbal commands; ventilatory and cardiovascular functions are unaffected.

Moderate sedation: Drug-induced depression of consciousness during which patients respond purposefully to verbal commands either alone or accompanied by light tactile stimulation; no intervention is necessary to maintain a patent airway and spontaneous ventilation is adequate; cardiovascular function is usually maintained.

Deep sedation: Drug-induced depression of consciousness during which patients cannot be easily aroused but respond purposefully

after repeated verbal or painful stimulation; the ability to maintain a patent airway may be impaired, and spontaneous ventilation may be inadequate; cardiovascular function is usually maintained.

General anesthesia: Drug-induced loss of consciousness during which patients are not arousable even by painful stimulation; patients often require assistance in maintaining a patent airway, and positive-pressure ventilation may be required; cardiovascular function may be impaired.

Although most practitioners would undoubtedly feel more comfortable with the idea of moderate sedation, the reality is that most procedures performed in the ED require deep sedation. However, regardless of the level of sedation desired, it is important to stress that these states represent different points on a continuum and that movement along this continuum can occur in either direction at any time. It is therefore imperative for practitioners to have the appropriate training and resources to intervene if a patient moves into a level of sedation deeper than intended. This training should include the ability to manage a compromised airway and use advanced resuscitation techniques.

PATIENT SELECTION AND MONITORING

Administration of sedatives and analgesics should occur in a facility suitable for appropriate evaluation and monitoring of patients, and for performing emergency resuscitative measures if needed. Monitoring and emergency equipment suitable for children of all ages and sizes must be available (Table 220.1). This should include a positive-pressure oxygen delivery system, suction apparatus, blood pressure monitor, pulse oximeter, and an emergency crash cart.

TABLE 220.1
Equipment

Positive-pressure oxygen delivery system
Suction apparatus
Blood pressure and CR monitor
Pulse oximeter
Emergency crash cart

CR, cardiorespiratory.

Capnography should be considered when deep sedation is planned. Capnography allows for continuous assessment of ventilatory status and can provide an early indication of airway or respiratory compromise. In addition, capnography avoids depending on the pulse oximeter's delayed detection of changes in oxygen desaturation.

Reversal agents should also be readily available. The practitioner responsible for monitoring the patient *must be someone other than the one performing the diagnostic or therapeutic procedure* and should be appropriately trained and certified.

A full evaluation of the patient's health and medical history should be performed, with consideration given to the patient's physiologic reserve defined by the ASA physical status classification (Table 220.2). Patients who are ASA class I or II are usually considered appropriate candidates for moderate or deep sedation in the ED. Patients in ASA class III or IV present special problems that involve additional considerations (4).

TABLE 220.2
American Society of Anesthesiologists Physical Status Classification

Class I	A healthy patient
Class II	A patient with mild systemic disease
Class III	A patient with severe systemic disease
Class IV	A patient with severe systemic disease that is a constant threat to life
Class V	An ill patient not expected to survive without an operation

Evaluation of the patient's recent food and fluid intake is recommended. Although there is no evidence supporting a

relationship between preprocedural fasting and incidence of adverse events during procedural sedation, current ASA and AAP guidelines recommend that patients undergoing elective sedation follow the same fasting guidelines as those for general anesthesia (Table 220.3). However, it may not be reasonable or acceptable to follow nil per os (NPO) guidelines in some emergent circumstances. Therefore, clinical judgment should be exercised, and the risks of aspiration versus the benefits of performing the procedure in a timely fashion should be carefully considered.

TABLE 220.3
Anesthesia Fasting Guidelines

Ingested Material	Minimum Fasting Period
Clear liquids	2 hrs
Breast milk	4 hrs
Formula, nonhuman milk	6 hrs
Light meal (BRATT diet)	6 hrs
Heavy meal	8 hrs

Thorough documentation of a PSA event should start with informed consent. During sedation, the patient's vital signs, medications, depth of sedation, and occurrence of unexpected events (Table 220.4) should be recorded. The frequency of documentation varies with the level of sedation. It is recommended that heart rate, blood pressure, and oxygen saturation be recorded prior to the sedation, every 5 minutes during moderate and deep sedation, and once again prior to discharge. After the procedure is completed and sedation is no longer desired, monitoring should continue until the patient has recovered sufficiently to meet the following discharge criteria:

TABLE 220.4
Documentation

Monitor	Document
Oxygenation	Consent
Ventilation	Vital signs
Airway	Oxygen saturation
Level of consciousness	Medications
	Untoward events
	Recovery

1. Cardiovascular function and airway patency are satisfactory and stable.
2. Patient is easily arousable and protective reflexes are intact.
3. Patient can talk and sit up (age-appropriate level).
4. Hydration is adequate and the patient can tolerate PO intake.

In general, patients should be monitored for up to 1 hour following completion of the procedure. During this time, vital signs should be monitored and recorded every 15 minutes. For the very young or special-needs child who is incapable of the usual expected responses, the presedation level of responsiveness or a level as close as possible to the child's baseline should be achieved prior to discharge. Appropriate discharge instructions specifically pertaining to PSA should be given to caretakers and include anticipatory guidance regarding sleep, diet, activity, safety precautions, and specific instructions on how to access care in the event of untoward effects or unexpected complications.

NONPHARMACOLOGIC THERAPY

The involvement of child life specialists in the management of pain and anxiety in the pediatric patient can be invaluable. By providing the patient with age-appropriate information regarding the procedures to be performed and teaching appropriate coping strategies, these specialists often succeed in lessening the child's fear and anxiety, thereby reducing and occasionally eliminating the need for any pharmacologic intervention. Distraction techniques such as listening to music with headsets, singing, or imagery can also be powerful coping strategies. Finally, parental support at the bedside can play a significant role in reducing the child's distress (5).

PHARMACOLOGIC THERAPY

There is currently no single agent available that possesses all of the qualities desired for optimal PSA in children. There are, however, many drugs that, when used alone or in combination for the right indications, are very effective and relatively safe. In selecting an agent, the physician must consider the effects desired, the risks and benefits, and the logistics of administration for each situation. When pure sedation is the desired end-point, agents such as benzodiazepines, barbiturates, and propofol should be considered. These agents do not inhibit perception of pain and should never be used as the sole agent when pain management is needed as part of the PSA. Purely sedative agents, however, can be used for painful procedures when used in conjunction with other agents that provide analgesia.

In contrast, nitrous oxide, ketamine, and sedating analgesics such as opioids are excellent choices for painful procedures. Although they provide varying degrees of sedation, they should rarely be used as single agents for nonpainful diagnostic studies. Combining different classes of agents is a way to produce an effect not present with either agent alone. Such combinations must be used with caution, however, for they may potentiate both desired responses and undesired adverse effects.

Pure Analgesics (Nonnarcotics)

Indications: relief of mild to moderate pain
Complications: gastritis, peptic ulcer disease

Specific Agents

Acetaminophen. Pure analgesic agent with antipyretic properties. The standard dose is 15 mg/kg every 4 hours; the agent can be given orally or rectally and can be combined with narcotics such as oxycodone and hydrocodone.

Ibuprofen: Nonsteroidal anti-inflammatory agent with analgesic and antipyretic properties. The standard dose is 10 mg/kg by mouth every 6 hours.

Ketorolac: Nonsteroidal anti-inflammatory agent best suited for relief of biliary and renal colic. The standard dose is 0.4 to 1.0 mg/kg intravenously (IV) or intramuscularly (IM).

Pure Sedatives

Indications: sedation for nonpainful diagnostic or therapeutic procedures

Complications: dose-dependent respiratory depression, hypotension, "paradoxical" (disinhibitory) effects

Specific Agents

Benzodiazepines

Midazolam: Potent sedative with amnesic and anxiolytic properties, rapid onset, and short duration of action (6).

The standard dose is 0.02 to 0.1 mg/kg IV, 0.5 to 0.7 mg/kg orally or rectally, and 0.3 mg/kg intranasally. Midazolam given orally, rectally, or intranasally is effective in providing anxiolysis. The intranasal route, using an appropriate atomizer, provides excellent and easily administered low-grade anxiolysis for a wide variety of applications, from IV starts and brief imaging studies to minor wound repairs. When titrating intravenously, onset of sedation may take 2 to 5 minutes. Children younger than 5 years of age can become excited and agitated when given midazolam (7). Whether this represents a paradoxical or disinhibitory effect and whether higher doses would eliminate the effect is unknown. IV and oral caffeine has successfully reversed this effect.

Barbiturates

Pentobarbital: Sedative agent best used intravenously for nonpainful diagnostic studies. The onset of action is within 1 to 2 minutes, with duration of 30 to 60 minutes, and the standard dose is 2 to 6 mg/kg IV. It is recommended to start with an initial dose of 2 mg/kg and titrate to effect with subsequent doses of 1 to 2 mg/kg every 30 seconds as needed.

Thiopental: Ultra–short-acting agent that can cause profound respiratory depression and hypotension. Standard dose is 3 to 5 mg/kg IV or 25 mg/kg rectally. In current EM practice it is rarely used.

Methohexital: Ultra–short-acting agent with dose-dependent respiratory depression and apnea but minimal associated cardiovascular side effects. Standard dose is 1 mg/kg IV.

Other Agents

Etomidate is an ultra–short-acting sedative hypnotic with no analgesic properties. It has an onset of action of <1 minute and duration of 3 to 5 minutes; cardiorespiratory effects are minimal. Standard dose is 0.1 to 0.3 mg/kg IV. Several studies have shown that etomidate is safe and effective when used in conjunction with analgesics for brief painful procedures (8).

Dexmedetomidine: Also known as precedex, this is a selective α_2-adrenoceptor agonist similar to clonidine, but with a much higher affinity for α_2-receptors than α_1-receptors. It produces "arousable sedation" in which patients experience clinically effective sedation yet are easily arousable. The initial dose of precedex is 3 μg/kg IV, administered over 10 minutes. This can be followed by a maintenance infusion of 2 μg/kg/hour. Precedex should not be given to infants <6 months of age or those with a history of acquired or congenital heart disease other than ASD, VSD and PDA, stroke, recent seizure, moyamoya disease, significant hepatic or renal failure, use of β-blockers, calcium channel blockers and digoxin, or allergy to clonidine. Episodes of bradycardia, hypotension, and sinus arrest have been associated with dexmedetomidine when administered rapidly IV (e.g., bolus administration) or with patients having high vagal tone. Use caution in patients with heart block, severe ventricular dysfunction, hypovolemia, diabetes, chronic hypertension, and in the elderly patients.

Propofol is an ultra–short-acting sedative hypnotic with no analgesic or amnestic properties. It has a rapid onset and brief

duration of action and is a potent antiemetic agent. It does, however, have a narrow therapeutic range with a slightly higher reported incidence of partial airway obstruction, apnea, and hypotension in comparison to other commonly used sedative agents (8). Standard initial dose is 1 to 2 mg/kg, followed by either additional boluses of 0.5 mg/kg or a constant infusion of 50 to 100 μg/kg/min. It can cause pain at the site of infusion and should not be administered to patients with egg or soy allergy. Multiple studies have shown that propofol is a safe and effective single agent for painless diagnostic studies (8) or in conjunction with opioid analgesics for painful procedures (9).

Chloral hydrate is a sedative hypnotic with a long history of safety in pediatrics. It can be given orally or rectally. Because of its unpredictable and variable onset and recovery profile (onset taking as long as 40 to 60 minutes) its practical utility in the ED is severely limited. It is also a known gastrointestinal irritant with arrhymogenic potential when given in the higher dose ranges. Children <6 months of age appear to be at increased risk of adverse events when compared to older children. The standard dose is 25 to 100 mg/kg orally or rectally with a maximum of 1 g for infants and 2 g for older children. For infants less than 2 months of age who require sedation, a dose of 35 to 50 mg/kg PO is recommended.

Sedative Analgesics

Indications: moderate to severe pain management, painful procedures

Complications: respiratory depression, nausea, vomiting

Specific Agents

Opioids

Morphine is the gold standard against which all other narcotics are compared. The standard dose is 0.1 to 0.2 mg/kg IV. The use of morphine as a single agent is not considered procedural sedation. As with most narcotics, dosing may vary depending on degree and extent of pain.

Fentanyl, the most potent of the conventionally used narcotics, has a rapid onset of action (1 to 10 minutes) and a relatively brief duration of 30 to 60 minutes. It has fewer respiratory and cardiovascular depressive effects than other opioids but can cause severe respiratory depression and apnea when combined with benzodiazepines. The standard dose is 1 to 2 μg/kg IV, administered slowly. Rapid boluses have been associated with chest wall rigidity and should be avoided (10). Although available in transmucosal form as a lollipop, the high incidence of nausea and vomiting has limited its acceptability (11). Fentanyl is an excellent choice as an intranasal agent given at 2 μg/kg via for rapid treatment of pain before an IV is established (e.g., minor partial thickness burn patient). The use of fentanyl as a single agent is not considered procedural sedation. For procedural sedation, fentanyl is often combined with either propofol or midazolam.

Nonopioids

Ketamine is unique among the sedative analgesics in that it produces a dissociative state between the thalamus and limbic systems, which is characterized by four features: sedation, analgesia, amnesia, and catalepsies (12). It possesses positive inotropic and bronchodilatory effects, with preservation of spontaneous respirations and protective airway reflexes. These qualities make it an ideal choice for outpatient procedures, with an excellent safety and efficacy record documented in more than 11,000 children (13). The standard dose is 1 to 2 mg/kg IV, 3 to 5 mg/kg IM, and 10 mg/kg PO. The clinical state produced by ketamine differs from other sedatives; the patient's eyes often remain open but with a disconnected stare and marked nystagmus. This "lights on, nobody home" look can be disconcerting to parents and they should be warned of this prior to administration of the drug. Potential side effects of ketamine may include increased salivary and tracheobronchial secretions and emergence reactions (13). Atropine (0.01 mg/kg; minimum, 0.1 mg; maximum, 0.5 mg) or glycopyrrolate (0.005 mg/kg; maximum, 0.25 mg) may help attenuate increased in secretions. Overall the literature describing increased secretions is not conclusive and

additional suctioning maybe all that is required to manage secretions. Emergence reactions are uncommon in children younger than 8 years. Whether the frequency of emergence reactions can be reduced by premedication with a benzodiazepine (e.g., midazolam 0.05 mg/kg) is controversial. A recent study concluded that the incidence of emergence phenomena was not affected by the addition of midazolam (14). Laryngospasm after administration of ketamine has been documented especially in small infants (younger than 3 months) with respiratory tract infections, and use of ketamine is therefore contraindicated in this patient population. In older patients laryngospasm is noted in approximately 1 in 256 patients (13). It is typically seen shortly after administration of the medication (with in 30 seconds) and can be managed with effective positive pressure ventilation via bag valve mask; the vast majority of episodes of laryngospasm will resolve within 10 to 20 seconds. A very small minority of patients will require paralysis with succinylcholine to terminate laryngospasm. Other contraindications include conditions associated with increased intracranial or intraocular pressure, hypertension, thyroid disease, and porphyria.

Inhalational Agents

Nitrous oxide is the only inhalational agent in common use in EM practice, usually in concentrations of 30% to 70% N_2O mixed with oxygen. Concentrations $<50\%$ generally provide analgesia only, with sedation occurring in concentrations $>50\%$. It is a safe, effective sedative–analgesic with a rapid onset and short duration of action upon withdrawal. Nitrous oxide is inexpensive and easy to administer by experienced personnel. “Setting the scene” is very important when using nitrous oxide in young patients. The patient must be well prepared in terms of expectations and be able to cooperate. This method of sedation is best used in older children and adolescents who are more likely to cooperate with the mask.

Reversal Agents

Reversal agents available for PSA include the following:

Naloxone (narcan): opioid antagonist (dose 0.01 to 0.1 mg/kg IV or IM)

Flumazenil (mazicon): benzodiazepine antagonist (dose 0.01 mg/kg IV, maximum 0.2 mg, repeated every 1 minute to a maximum of 3 mg)

Topical Anesthetic Agents

LET: Topical solution of 4% lidocaine, 0.1% epinephrine, and 0.5% tetracaine. It should be applied directly into the wound and has an onset of action of 20 to 30 minutes. It should not be applied to areas where vasoconstriction is a concern. It can be made into a gel form with the addition of hydroxyethyl cellulose.

EMLA: Eutectic mixture of 2.5% lidocaine and 2.5% prilocaine. It should be applied to intact skin with an occlusive dressing and has an onset of action of 60 minutes.

LMX-4: Formulation of 4% lidocaine in a liposomal delivery system. It should be applied to intact skin with an occlusive dressing and has an onset of action of 30 minutes.

Common Pitfalls

- Insufficient monitoring during and after procedural sedation.
- Failure to assure that the provider responsible for monitoring the patient does not become involved in performing the procedure.
- Providing only a sedative agent for a painful procedure without providing analgesia.
- Giving insufficient medication because of time factors or fears about side effects, especially respiratory depression.
- Selecting an agent that cannot be titrated quickly enough and thus fails to produce the desired state.
- Failing to have reversal agents readily available.
- Failing to anticipate disinhibitory effects with the use of benzodiazepines in small children.
- Failing to prepare parents for the nystagmus and catalepsy seen with ketamine.

PART 3 • CHIEF COMPLAINTS

CHAPTER 221 Neonatal Jaundice

Margaret Wolff

Jaundice is defined as a yellow discoloration of the skin and sclerae indicative of excessive bilirubin production or disordered bilirubin metabolism or excretion. When the serum concentration of bilirubin exceeds 2 mg/dL, jaundice usually becomes apparent and is best appreciated on the palms and soles (1). The etiologies of neonatal jaundice range from physiologic jaundice to potentially life-threatening conditions. These can be differentiated by a thorough history, physical examination, and laboratory evaluation. This chapter discusses the diagnostic approach to a young infant with jaundice. For the approach to patients greater than 8 weeks of age, see Chapter 102 (jaundice).

Bilirubin is created from the breakdown of hemoglobin and other heme-containing proteins. Bilirubin produced by this degradation process is unconjugated and poorly water soluble. Unconjugated bilirubin is conjugated in the liver with glucuronic acid (which is water soluble) and excreted into the biliary tract and in the stool (Fig. 221.1).

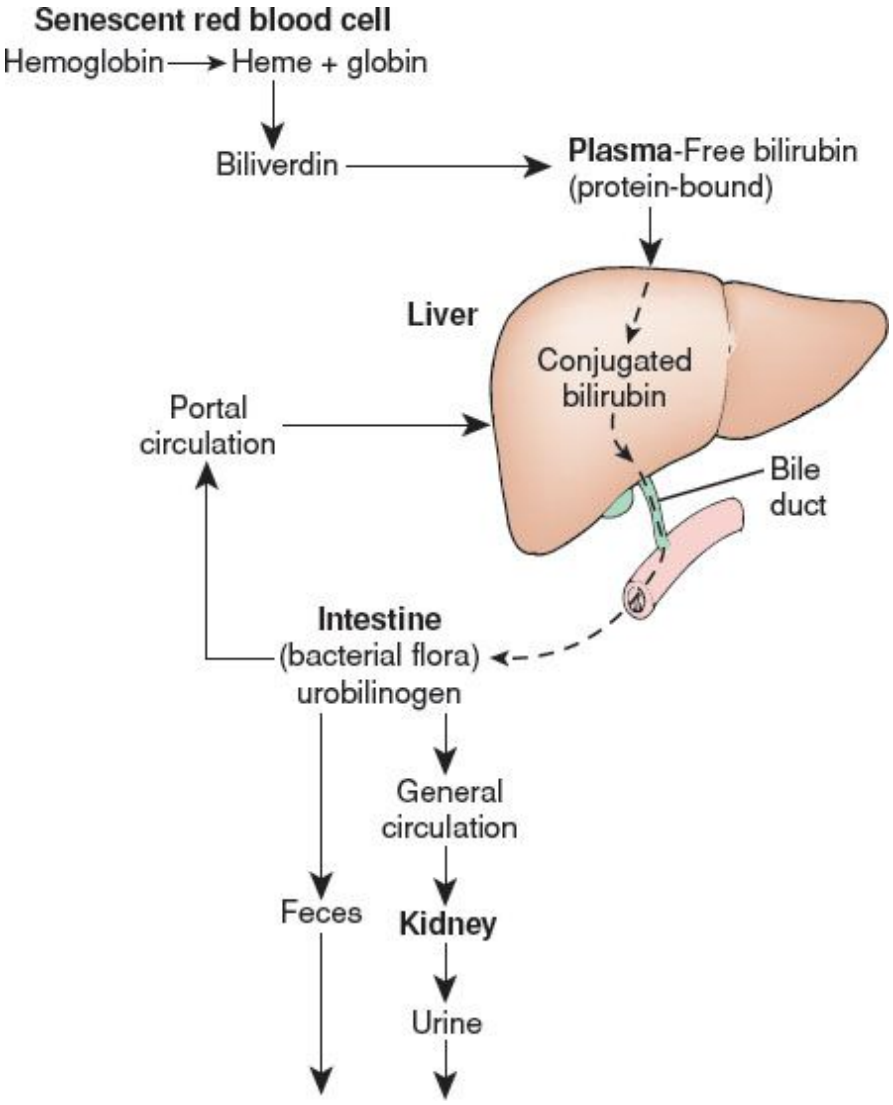

FIGURE 221.1 The process of bilirubin formation, circulation, and elimination. (Image from Porth CM. Pathophysiology: Concepts of Altered Health States. 7th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2005.)

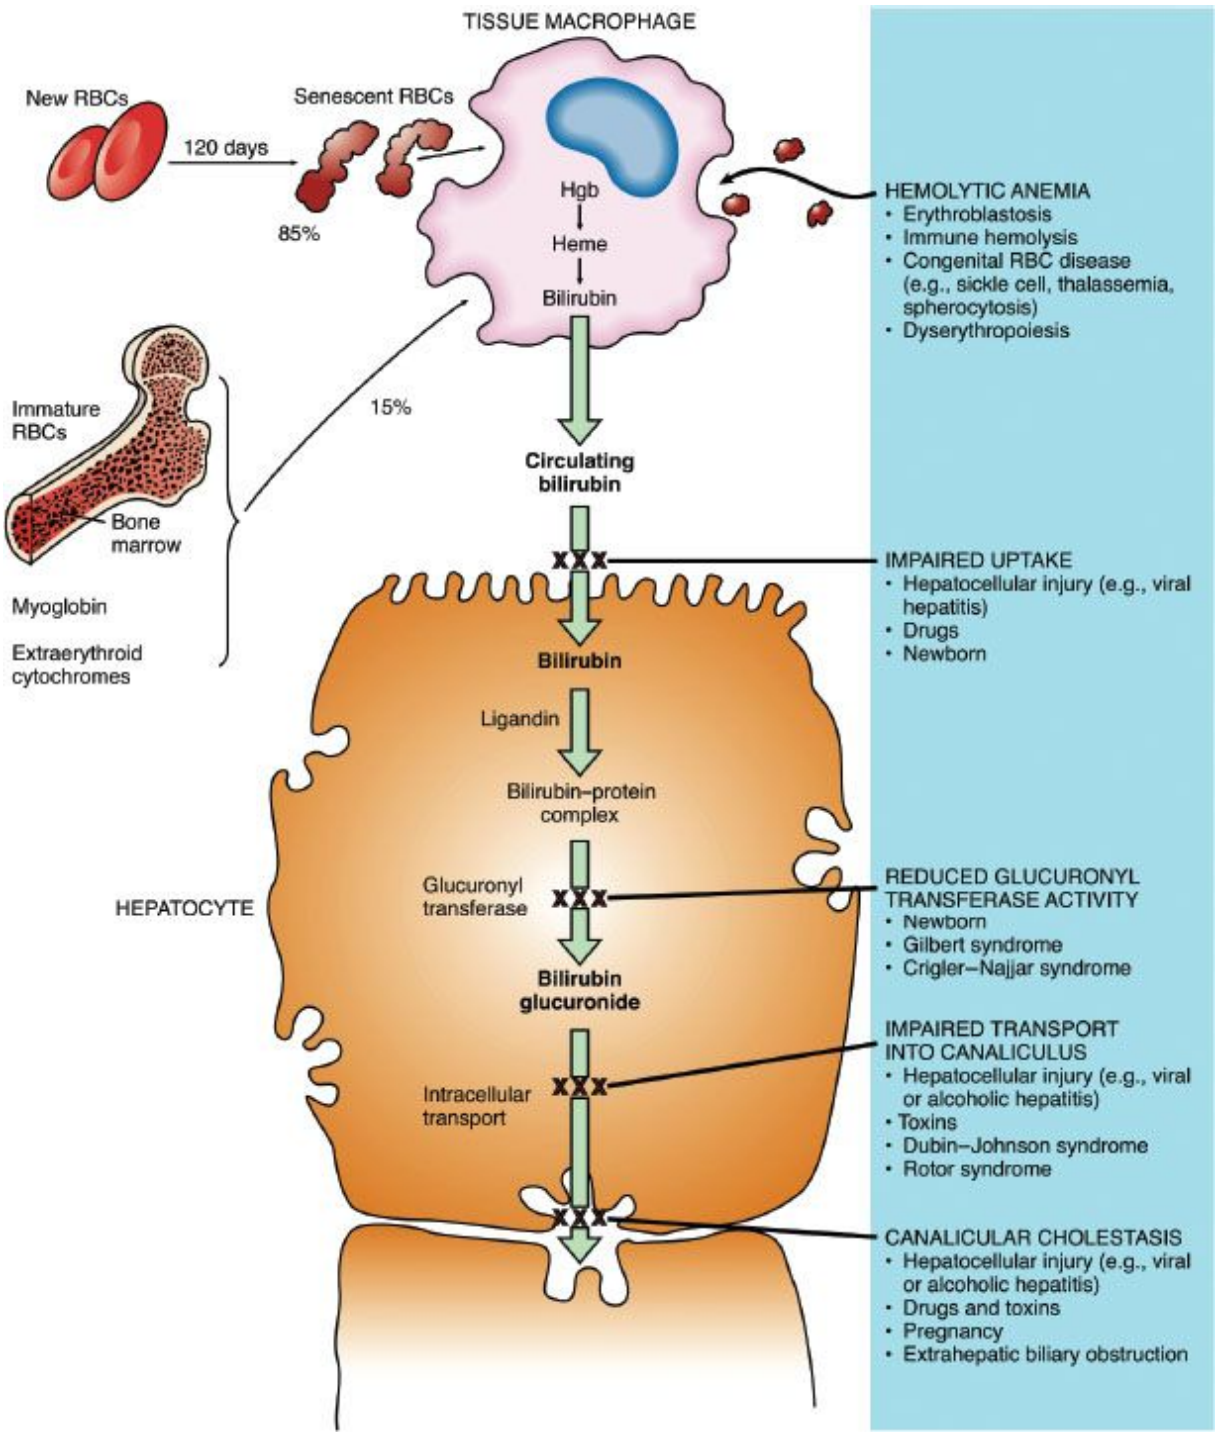
CLINICAL PRESENTATION

Almost all neonates will have some degree of jaundice in the first week of life but are otherwise well appearing (2). Some of these neonates may appear dehydrated or have significant reduction in weight from birth weight suggesting insufficient oral intake. Other findings may suggest a more concerning cause of neonatal jaundice.

- Temperature instability, lethargy, apnea, or poor feeding suggest a serious bacterial infection (3)
- Pallor may indicate anemia
- Jaundice and vomiting suggest upper gastrointestinal obstruction
- Acholic stools suggest biliary tract obstruction
- Hepatomegaly may be associated with liver dysfunction
- Splenomegaly may indicate a hypersplenic state
- Neonates with acute bilirubin encephalopathy (kernicterus) may present with lethargy, hypotonia, and poor suck in the initial stages, and irritability and hypertonia in more advanced stages (4)
- Infants who present after the first 2 weeks of life with jaundice have pathologic jaundice and must be fully evaluated to determine the cause. These infants may be otherwise well appearing without any associated symptoms or they may exhibit any of the above signs and symptoms

DIFFERENTIAL DIAGNOSIS

Jaundice can be grouped based on underlying pathophysiology into the following categories: (1) excessive bilirubin production, (2) disordered bilirubin metabolism, or (3) disordered excretion (cholestasis) (eFig. 221.1). The majority of neonates develop some degree of jaundice due to a relative deficiency of glucuronic acid in the liver until approximately 14 weeks of age (5). In addition, neonates have more red blood cells and a shorter red cell half-life, resulting in increased bilirubin production compared to older children (6). This benign jaundice is termed physiologic neonatal hyperbilirubinemia and results in peak unconjugated bilirubin levels between 3 and 5 days that resolves without treatment. Breastfed neonates may develop breastfeeding-associated jaundice in the first week due to mild dehydration because of a delay in the let-down of breast milk as it transits from colostrum. Breastfed infants may also develop mild jaundice after the first week of life termed breast-milk jaundice due to effects of breast milk on intestinal excretion and resorption of bile (7).



eFIGURE 221.1 Mechanisms of jaundice at the level of the hepatocyte. Bilirubin is derived principally from the senescence of circulating red blood cells, with a smaller contribution from the degradation of erythropoietic elements in the bone marrow, myoglobin, and extraerythroid cytochromes. Jaundice results from overproduction of bilirubin (hemolytic anemia) or defects in its

hepatic metabolism. The locations of specific blocks in the metabolic pathway of bilirubin in the hepatocyte are illustrated. (Image from Rubin E, Farber JL. *Pathology*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999.)

Nonphysiologic hyperbilirubinemia is defined as jaundice in the first 24 hours of life, a rapidly rising bilirubin level, a bilirubin level exceeding phototherapy thresholds, jaundice that persists after 2 weeks, or conjugated hyperbilirubinemia (Table 221.1). Nonphysiologic jaundice may be caused by an exaggeration of the mechanisms that produce physiologic jaundice, or may be due to pathologic conditions leading to excessive bilirubin production, disordered bilirubin metabolism, or disordered excretion (cholestasis). After the neonatal period, excessive production from hemolysis is the most common cause of unconjugated hyperbilirubinemia (Table 221.2).

TABLE 221.1
Causes of Jaundice in Neonates

Physiologic hyperbilirubinemia

Breastfeeding-associated jaundice

Breast-milk jaundice

Nonphysiologic hyperbilirubinemia

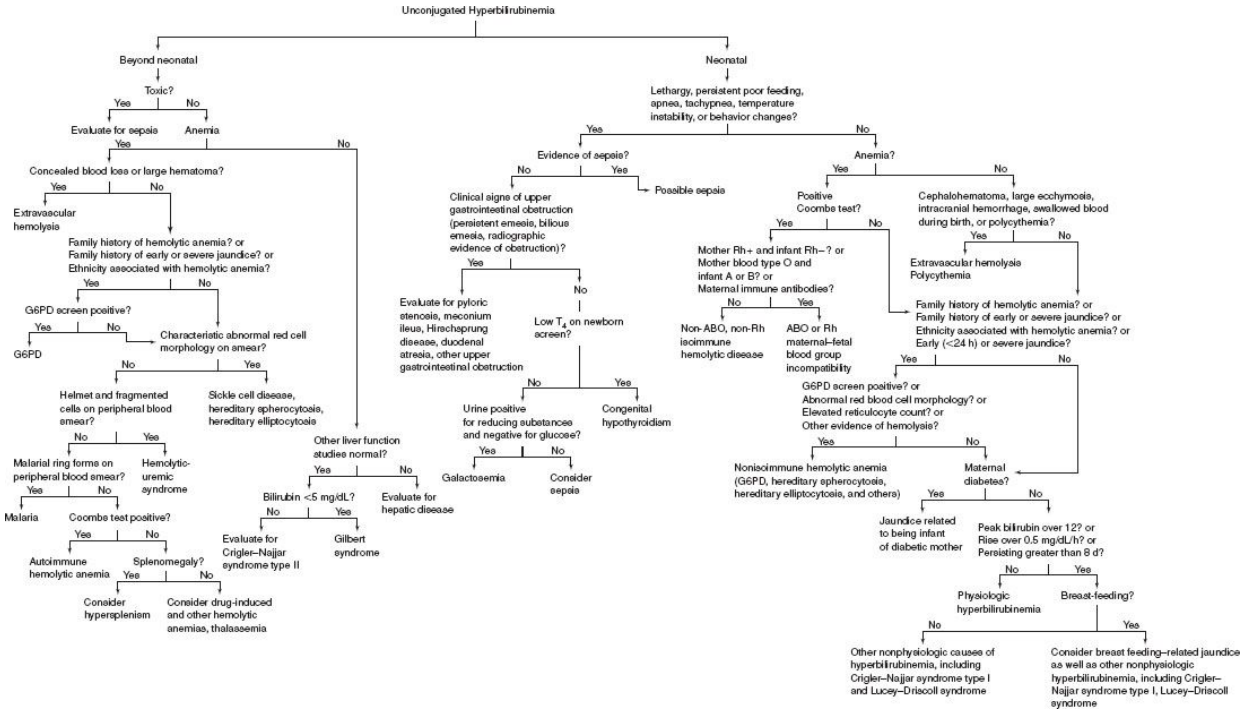
- **Excessive bilirubin production (unconjugated hyperbilirubinemia)**
- Intravascular hemolysis
  - Maternal–fetal blood group incompatibility
  - Polycythemia
- Extravascular hemolysis
  - Extravasated blood (cephalohematoma)
- **Disordered bilirubin metabolism (unconjugated hyperbilirubinemia)**
- Upper gastrointestinal obstruction
  - Hirschsprung disease
  - Pyloric stenosis
- Hypothyroidism
- Inherited disorders
  - Crigler–Najjar syndrome
  - Galactosemia
- **Cholestasis (conjugated hyperbilirubinemia)**
  - Biliary atresia
  - Metabolic disorder
  - Perinatal infections

ED EVALUATION AND MANAGEMENT

The emergency physician must distinguish neonates with nonphysiologic jaundice, who require treatment, from neonates who have benign self-limited causes of jaundice. If left untreated, high levels of bilirubin are associated with kernicterus, a chronic form of bilirubin encephalopathy characterized by permanent neurologic damage (8). Although kernicterus is rare, recent cases demonstrate the need for vigilance when evaluating these infants (9,10). Unfortunately, visual determination of bilirubin levels in neonates is unreliable, making laboratory testing necessary (11,12).

Since the majority of well-appearing neonates will have physiologic jaundice that does not require further treatment (eFig. 221.2), it is reasonable to obtain an initial fractionated bilirubin level from a heelstick capillary sample (13). If this demonstrates

hyperbilirubinemia with predominantly unconjugated bilirubin, the next step is to determine if phototherapy treatment is required, based on AAP Guidelines (Fig. 221.2). Patients requiring phototherapy should have more formal laboratory studies ordered, including a complete blood count, peripheral blood smear, blood type, and Coombs test. Neonates with bilirubin levels below the phototherapy threshold should be risk stratified to determine the near-term risk of hyperbilirubinemia (Fig. 221.3). Follow-up and repeat testing should be arranged as needed (4). In the rare instance that bilirubin levels indicate the need for an exchange transfusion, the decision should be made expeditiously after consultation with a neonatologist (Fig. 221.4). Patients who ultimately require exchange transfusion should be hospitalized and have phototherapy initiated promptly.



eFIGURE 221.2 Approach to the patient with unconjugated hyperbilirubinemia. TORCH, toxoplasmosis, other (infections), rubella, cytomegalovirus (infection), and herpes (simplex) (titer). (From Fleisher GR, Ludwig S, Henretig FM, et al., eds. *Textbook of Pediatric Emergency Medicine*. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2005.)

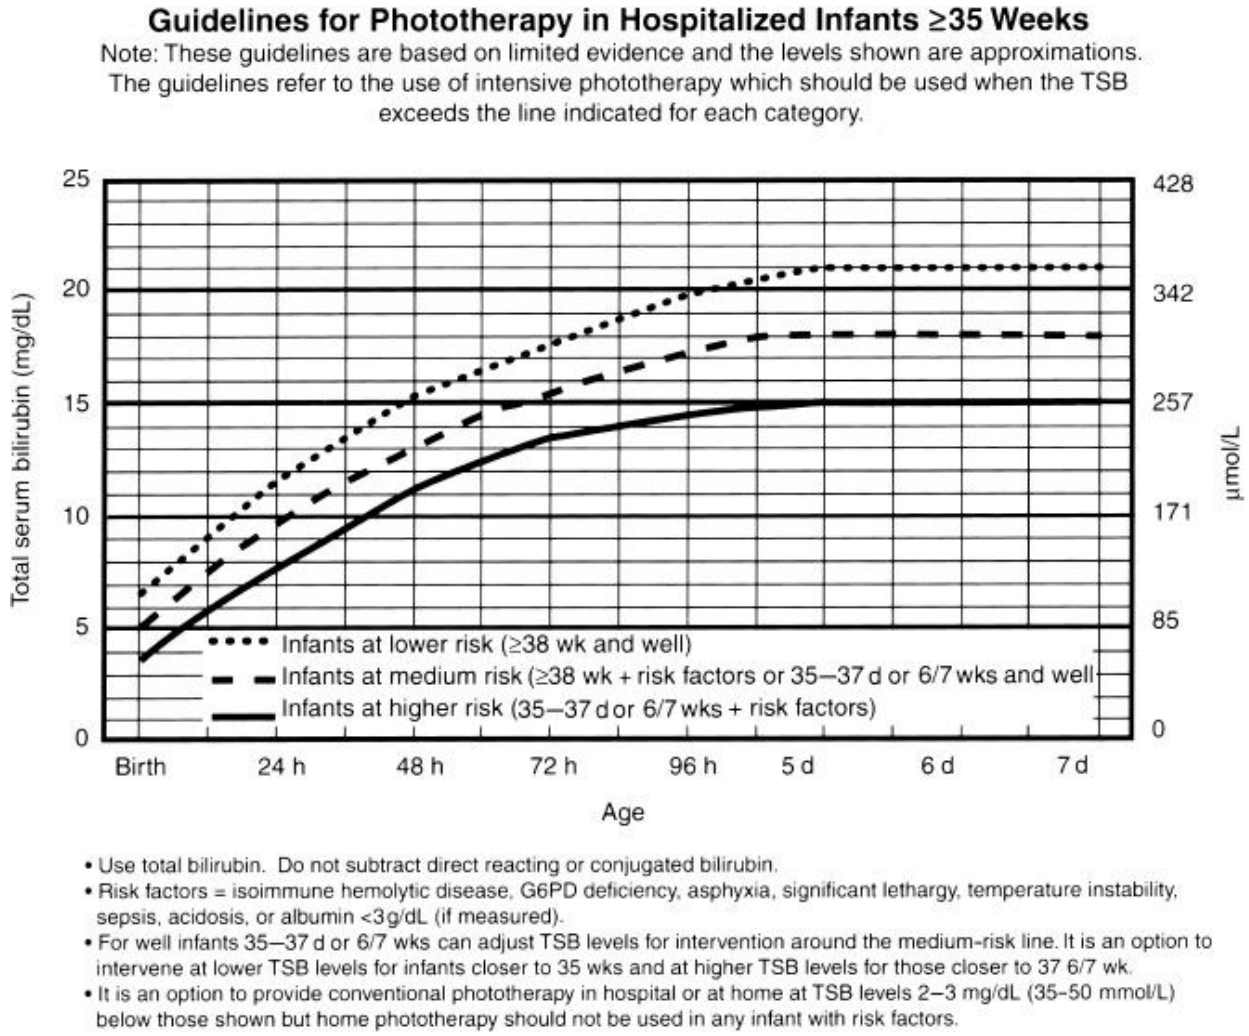


FIGURE 221.2 Management of hyperbilirubinemia in the newborn infant of 35 or more weeks of gestation. AAP guidelines for phototherapy in hospitalized infants of 35 or more weeks of gestation. Note: These guidelines are based on limited evidence and the levels shown are approximations. The guidelines refer to the use of intensive phototherapy which should be used when the TSB exceeds the line indicated for each category. Infants are designated as “higher risk” because of the potential negative effects of the conditions listed on albumin binding of bilirubin the blood–brain barrier, and the susceptibility of the brain cells to damage by bilirubin. (From MacDonald MG, Mullett MD, Seshia MMK. *Avery’s Neonatology: Pathophysiology and Management of the Newborn*. 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2005.)

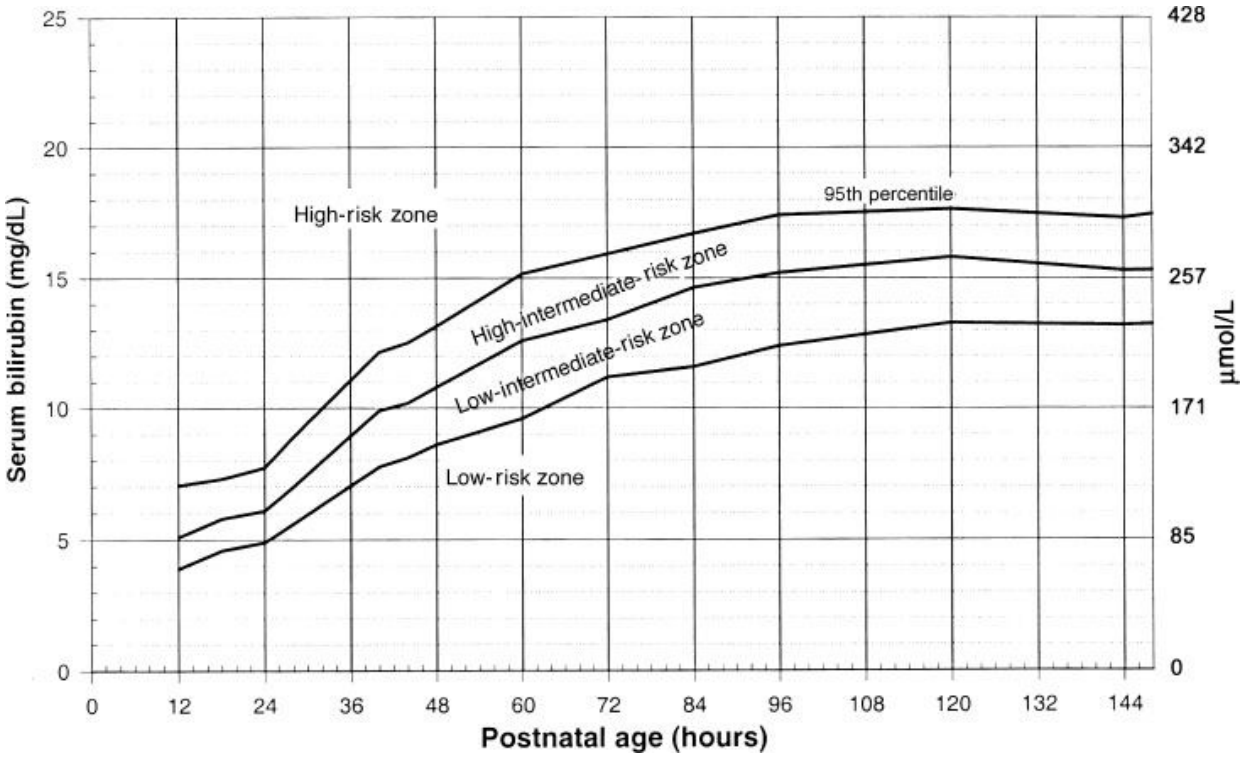

FIGURE 221.3 Nomogram for designation of risk in 2,840 well newborns ≤36 weeks of gestational age with birth weight ≤2,000 g or ≤35 weeks of gestational age and a birth weight ≤2,500 g or more based on the hour-specific serum bilirubin values. The serum bilirubin level was obtained before discharge, and the zone in which the value fell predicted the likelihood of a subsequent bilirubin level exceeding the 95th percentile (high-risk zone). (From MacDonald MG, Mullett MD, Seshia MMK. *Avery's Neonatology: Pathophysiology and Management of the Newborn.* 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2005.)

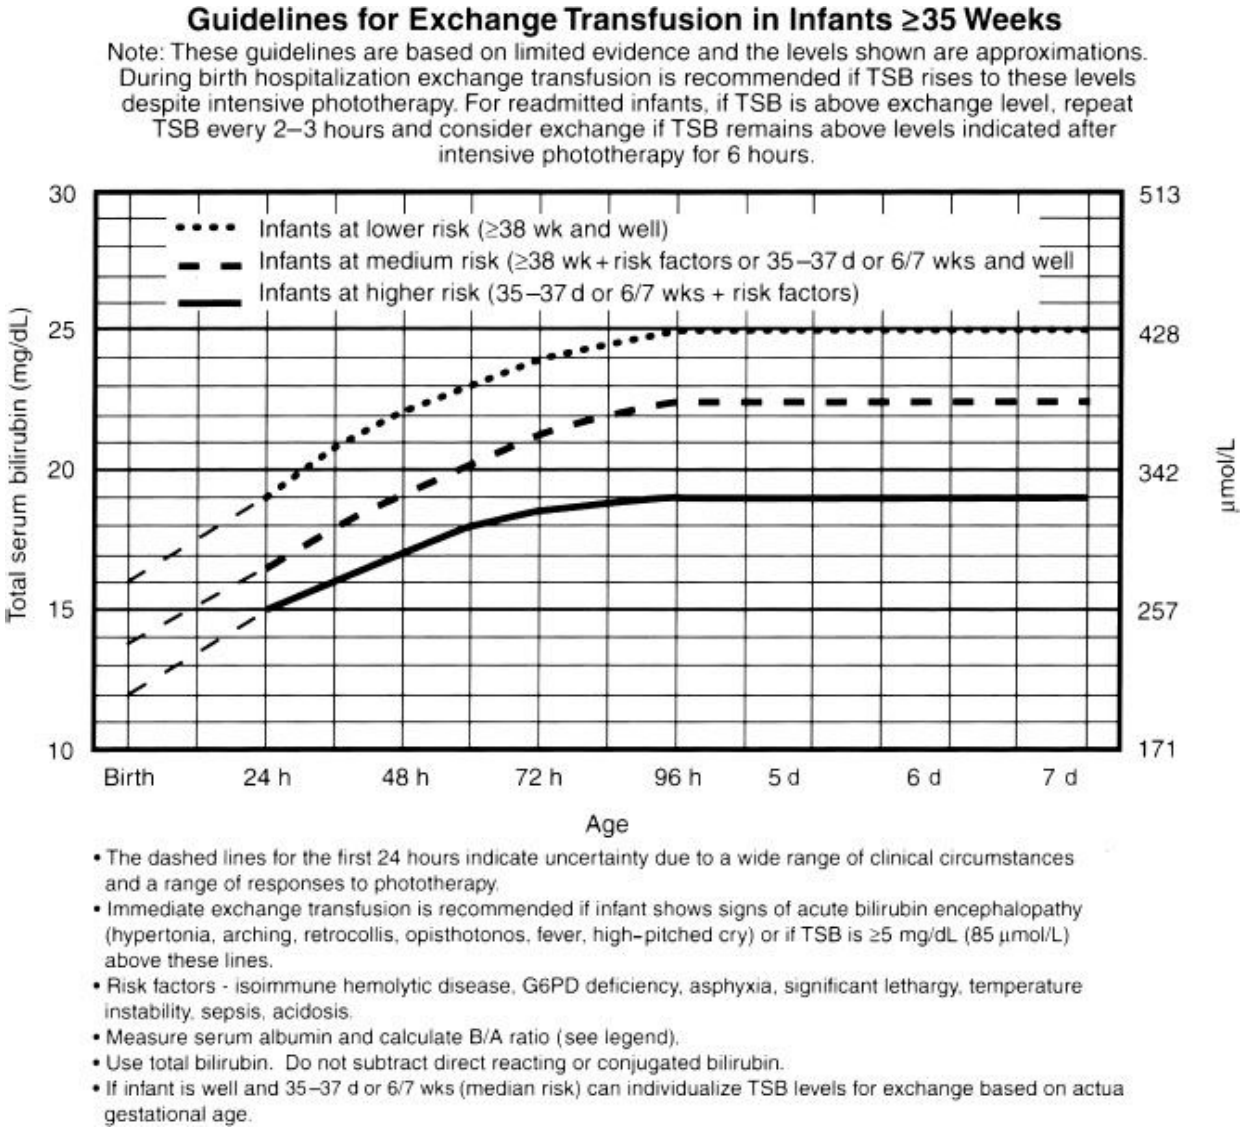

FIGURE 221.4 AAP guidelines for exchange transfusion in infants who are 35 or more weeks gestation. Note that these suggested levels are based on limited evidence, and the levels shown are approximations. During birth hospitalization, exchange transfusion is recommended if the TSB rises to these levels despite intensive phototherapy. For readmitted infants, if the TSB level is above the exchange level, repeat TSB measurement every 2 to 3 hours and consider exchange if the TSB remains above the levels indicated after intensive phototherapy for 6 hours. (From MacDonald MG, Mullett MD, Seshia MMK. *Avery's Neonatology: Pathophysiology and Management of the Newborn.* 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2005.)

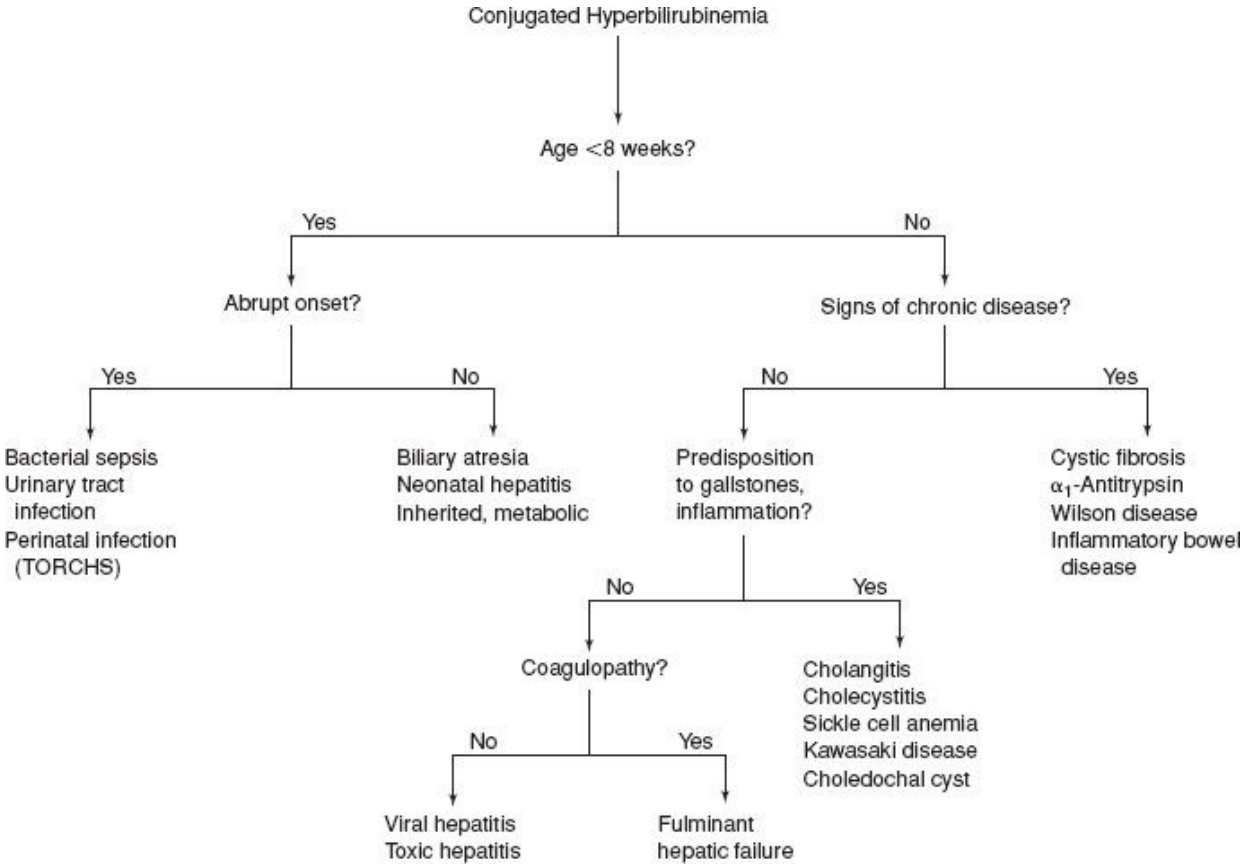
Laboratory evaluation consistent with conjugated hyperbilirubinemia (conjugated bilirubin >1 mg/dL when total bilirubin is <5 mg/dL or more than 20% of total bilirubin if the total bilirubin is ≤5 mg/dL) should prompt an evaluation for an underlying cause (eFig. 221.3) (14). If the onset was abrupt, consider perinatal TORCHS infections (i.e., toxoplasmosis, other infections, rubella, cytomegalovirus, herpes simplex, and syphilis), bacterial sepsis, and urinary tract infections (15). If the neonate appears well and does not have evidence of perinatal or bacterial infection, a urinalysis and urine culture should be ordered since a conjugated hyperbilirubinemia may be an early sign of neonatal urinary tract infection.



eFIGURE 221.3 Evaluation of the pediatric patient with unconjugated hyperbilirubinemia. (From Fleisher GR, Ludwig S, Henretig FM, et al., eds. *Textbook of Pediatric Emergency Medicine*. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2005.)

Infants with biliary atresia usually present with gradual onset of jaundice and acholic stools. However, it is important to maintain a high index of suspicion for biliary atresia in *any* neonate presenting with conjugated hyperbilirubinemia (16). Other disorders to consider when there is a more insidious onset of conjugated hyperbilirubinemia include metabolic disorders, and viral hepatitis. Laboratory studies will assist in assessing the degree of hepatocyte injury and biliary dysfunction (serum alanine aminotransferase and aspartate aminotransferase, serum alkaline phosphatase, and gamma-glutamyl transpeptidase) as well as the biosynthetic function of the liver (prothrombin and partial thromboplastin time, serum albumin, glucose, and ammonia). Newborn screening for thyroid disease and galactosemia should be reviewed and an ultrasound of the liver and biliary tract ordered. An extensive evaluation is often required in these patients and consultation with a pediatric gastroenterologist can guide additional testing and treatment. Phototherapy is relatively contraindicated in neonates with conjugated hyperbilirubinemia due to its association with bronze baby syndrome (4).

For infants who present after the first 2 weeks of life with jaundice, measure the total and conjugated bilirubin level to assess for evidence of cholestasis. For exclusively breastfed infants with no history of dark urine or acholic stools, a normal physical examination and reliable follow-up can have this evaluation deferred until 3 weeks of age. If the conjugated bilirubin is elevated, check the results of the newborn screen and evaluate for causes of cholestasis (see above) (4,17). Infants with elevated unconjugated bilirubin levels may be diagnosed with breast-milk jaundice, if they are exclusively breastfed and are otherwise well appearing. For these patients close follow-up should be ensured, however (Table 221.2).

TABLE 221.2
Causes of Jaundice After the Neonatal Period

Excessive Bilirubin Production (Unconjugated Hyperbilirubinemia)
Intravascular hemolysis
Autoimmune hemolytic anemia
Drug-induced hemolytic anemia
Infection
Bacterial sepsis
Malaria
Inherited red blood cell disorders
Microangiopathic hemolytic anemia
Extravascular hemolysis
Hypersplenism
Large hematomas
Disordered Bilirubin Metabolism (Unconjugated Hyperbilirubinemia)
Impaired hepatic bilirubin uptake
Drugs
Heart failure
Viral hepatitis
Impaired bilirubin conjugation
Inherited
Crigler–Najjar syndrome
Gilbert syndrome
Acquired
Drugs
Hyperthyroidism
Liver disease
Cirrhosis
Chronic hepatitis
Cholestasis (Conjugated Hyperbilirubinemia)
Intrahepatic
Hepatotoxins
Viral hepatitis
Metabolic disorders
Nonalcoholic steatohepatitis
Primary biliary cirrhosis
Sepsis
Extrahepatic (biliary obstruction)
Choledocholithiasis
Cholecystitis
Choledochal cyst
Pancreatitis
Primary sclerosing cholangitis

CRITICAL INTERVENTIONS

- Neonates presenting with temperature instability, lethargy, apnea, or poor feeding require prompt evaluation for possible sepsis and initiation of antibiotics and resuscitative efforts, as indicated.
- For neonates who meet phototherapy threshold criteria, intensive phototherapy should be initiated promptly.
- Neonates with severe hyperbilirubinemia who meet criteria for exchange transfusion require emergent transfer to a critical care setting where exchange transfusion can be initiated.

DISPOSITION

Neonates who are ill appearing or meet criteria for phototherapy or exchange transfusion require admission for treatment. Well-

appearing neonates with unconjugated (physiologic) hyperbilirubinemia that do not meet the threshold for phototherapy can be discharged home if close follow-up and repeat testing as indicated by risk assessment can be ensured. The majority of young infants with conjugated hyperbilirubinemia will require hospitalization for further diagnostic evaluation.

Common Pitfalls

- Visual determination of bilirubin level in neonates is unreliable; laboratory evaluation should always be performed to determine bilirubin level.
- Jaundice may be the initial presentation of serious bacterial infections in neonates.
- If a neonate's bilirubin level does not meet the phototherapy threshold, determine risk for subsequent significant hyperbilirubinemia and ensure necessary follow-up prior to discharge.

CHAPTER 222

Fever

Maureen D. McCollough and David A. Talan

Fever accounts for up to 30% of all visits presenting to pediatric emergency departments (EDs) or primary care providers, making it one of the most common chief complaints (1,2). Fever as a symptom is steeped in generations of myth and anecdotal folklore that has contributed to persistent misunderstandings and fever phobia. Studies addressing the topic of fever phobia in 1992, 2001, and 2010 touched upon a set of recurring themes (1). Among these were large number (91%) of parents who believed in the potential permanent harm fevers could cause, including brain damage (21%) and death (14%). Most importantly, among the 56% of respondents who considered themselves very worried about fever, there was a higher likelihood of having had a child who had undergone an evaluation for fever in which blood work was drawn and the treating physician seemed very worried about the fever (1). Parents' notions and attitudes regarding fever are often modeled on the attitudes of clinicians who have cared for febrile children. Rational evidence-based approaches to fever in young children are vital to providing care that treats fever like a symptom and not a disease. This chapter presents an approach to fever in otherwise well-appearing or mildly ill children stratified by age: 0 to 28 days, 29 to 56 days, and greater than 8 weeks of age.

CLINICAL PRESENTATION

Fever represents a physiologic response, at the level of the hypothalamus, to bacterial or viral agents and their associated by-products (i.e., endotoxin). An alteration of the body's set point

results in an elevation of core temperature that creates a less hospitable environment for infectious microorganisms. The elevated temperature retards bacterial growth, enhances neutrophilic action, and promotes the acute-phase immune response. Since fever is a natural response to infection, many have questioned the utility of antipyretics. Fever already been stated may promote insensible water loss that leads to frank dehydration. Antipyretics are thus still advocated for children who are symptomatic from the fever, but clinicians should not gauge the likelihood of bacterial illness by the degree of response to antipyretic therapy, since there is no association between the two (7). Fever secondary to infection is not generally harmful unless the temperatures rise above approximately 106.5˚F (1). One of the most significant misconceptions among parents and caregivers concerns what to consider a high fever. Approximately 7% felt that fevers could reach 43.4˚C (110˚F), and 44% felt that a fever of 38.9˚C was a high fever. Fever anxieties also manifest themselves in how antipyretics are used; 44% of caregivers who administered either acetaminophen or ibuprofen did so at too frequent dosing intervals, which could result in either hepatic or renal damage.

Clinicians must educate caregivers on how to appropriately approach and treat fevers in their children. The first step is to prioritize patient appearance over height of fever. A happy and playful infant with a fever of 40˚C is of less concern than a lethargic child who has a fever of 38.5˚C. In evaluating young febrile children, the patient's age and overall appearance, and presence or the absence of a clinically suspected source of infection, are the most important factors in determining the need for further diagnostic testing. Although the degree of fever is important, it *must* be considered within the clinical context and not as the sole factor. The features of an ill appearance include altered mental status, poor eye contact, lethargy, and poor muscle tone. An elevated fever ($>$40˚C, 104˚F) can make a child appear quiet and unhappy but should not necessarily result in an ill appearance. Other important factors to consider are the patient's vaccination history, any underlying

conditions (e.g., HIV, cancer, prematurity), and the availability of follow-up.

Signs of serious illnesses such as meningitis can be subtle. Assessing behavior in young children and infants in particular can be difficult, even for experienced examiners. In a patient with an equivocal presentation, observation of trends in behavior over time, including alertness, consolability, social interactions, and feeding, is the most sensitive means of discerning the presence of a serious infection. When follow-up is uncertain, a more extensive evaluation and a more cautious disposition may be justified.

Traditionally, a rectal temperature (for neonates and young children) of ≤38°C (100.4°F) has been defined as fever. There is some debate surrounding these numbers, but the variation is relatively narrow, within 1 to 2 tenths of a degree. Bundling of an afebrile child should not cause a significant fever when the temperature is taken rectally (3). Axillary temperatures, as well as other methods measuring temperature over the forehead or temporal artery, have been shown to vary widely when compared with rectal temperature (4). Patients frequently present with a history of tactile fever. In one study, patients with reported tactile fever who were noted to be afebrile in the ED were at low risk for fever in the subsequent 48 hours (5). Recent antipyretic use may interfere with the identification of fever, although fever is typically not entirely eliminated, and the antipyretic effects begin to dissipate approximately 2 hours following the most recent dose (6).

DIFFERENTIAL DIAGNOSES

Fever is not always infectious in origin. Noninfectious causes (Table 222.1) must also be considered. Table 222.2 presents an approach to the evaluation of the acutely febrile infant or child based on the child's age and assuming the absence of underlying conditions and reliable follow-up.

TABLE 222.1
Noninfectious Causes of Acute Fever in Infancy and Childhood

Environmental

Overbundling (may raise skin temperature but not rectal temperature to highly febrile range) (13)

Heat stroke

Collagen vascular disease

Rheumatic fever (prolonged fever, recent sore throat, rash, arthralgia)

Juvenile rheumatoid arthritis (prolonged fever, rash, arthritis)

Poisoning

Atropine or other anticholinergics (dry mucous membranes, flushed)

Salicylates (tinnitus, hyperventilation)

Amphetamines (pupillary dilation, agitation, tremor, hypertension, tachycardia, hyperreflexia)

Antidepressants

Other

Kawasaki disease (prolonged fever, conjunctivitis, rash, adenopathy, erythematous mucous membranes)

Drug reaction

Prolonged seizures

Hemolysis

TABLE 222.2
Evaluating the Acutely Febrile Child

Age	
<28 d[b,c]	Septic workup,[d] empiric antimicrobials, supportive care and monitoring, and hospital admission
1–2 mos[b]	Septic workup[d]
	Ill-appearing infants[e] or those with positive septic workup or not meeting Philadelphia, Boston, or Rochester criteria (**Tables 222.4–222.6**) should receive empiric antimicrobials, supportive care and monitoring, and hospital admission
	If nontoxic with a negative septic workup (i.e., meeting low-risk criteria), discharge home with close follow-up with or without intramuscular antibiotics[d]
2–24 mos	Ill-appearing[e] infants and young children should undergo a septic workup and receive empiric antimicrobials, supportive care and monitoring, and hospital admission
	Additional laboratory workup and management considerations in this age group are dependent on general appearance and change over time and specific physical findings, such as meningismus or bulging fontanelle (e.g., lumbar puncture), painful swollen joint (e.g., arthrocentesis), petechial rash (e.g., possible meningococcemia requiring parenteral antimicrobials and hospital admission), or prolonged gastroenteritis (e.g., possible enteric pathogens)
	Additional laboratory workup and management will also be influenced by the child's medical history especially for immunocompromised states such as sickle cell anemia or cancer
	If nontoxic-appearing, temperature >39°–39.5°C,[f] and no source on examination[g] consider:
	UA and UC for girls <2 yrs old and for uncircumcised boys <6–12 mos old
	Chest x-ray if signs of lower respiratory tract disease are present
	If no infectious source is identified, in a well-appearing child, blood cultures and empiric antibiotics are generally no longer recommended in children who have received at least two sets of HiB and pneumococcal vaccinations. For unvaccinated or undervaccinated well-appearing children thought to be at risk of occult bacteremia (e.g., high fever or WBC count), consider blood cultures, with or without empiric antibiotics (e.g., ceftriaxone), and close follow-up
>24 mos	History and physical examination are usually reliable to identify presence of serious (e.g., meningitis or septic shock) or localized infection, and will dictate the extent of laboratory workup and management. UA and UC should be considered for girls if no source found on examination, or if vomiting, abdominal pain, or tenderness exists

[a]Simplified approach to evaluation of fever; many variables must be taken into account, including prematurity, past medical conditions, ability to follow-up.
[b]Fever defined as 38°C in this age group.
[c]Age is defined as postterm age; body weight and past medical conditions should be considered when determining category for workup.
[d]CBC, blood culture, urinalysis (UA), urine culture (UC), stool for WBCs and culture if diarrhea, chest x-ray if symptoms or signs of lower respiratory infection are present. Lumbar puncture and CSF analysis recommended <1 month of age; 1–2 months of age optional but should be strongly considered even if no signs of CNS infection are present, and especially if antimicrobials are to be prescribed.
[e]Ill-appearing infant or young child is defined as having altered mental status, unresponsiveness, poor eye contact, lethargy, or limp tone. Dehydration alone can also present as an ill-appearing child. Highly elevated temperatures can make children appear unhappy but should generally not present as ill-appearance.
[f]The risk of bacterial infection as a cause for the fever increases with the degree of temperature elevation.
[g]Otitis media, upper respiratory infections, and gastroenteritis are not necessarily considered reliable sources of fever, such that other diagnoses can be excluded.

ED EVALUATION AND MANAGEMENT

To understand how febrile infants are risk-stratified, one must appreciate the historical context of our current practice. In the 1980s, prior to the introduction of the *Haemophilus influenzae* type b [HiB] and Prevnar vaccines, all febrile infants, in many cases up to 12 weeks of age, were routinely admitted to the hospital for a complete septic evaluation and treatment. Studies from the late 1980s and early 1990s generated evidence that made it possible to better stratify the risk of serious bacterial infection and narrowed the population of patients at greatest risk to 8 weeks and under; with infants less than 28 days remaining at highest risk (14–17).

All children evaluated for fever should receive a thorough physical examination. The initial examination should start with an evaluation of the child's ABCs. Signs of respiratory distress, hypoperfusion, or shock should be treated immediately. The child's mental status and interaction with the environment are especially important. Febrile children should be undressed to look for skin infections and rashes, including petechiae (e.g., meningococcemia) and vesicles (e.g., *Coxsackie* or *Varicella* infection). Testing the gait of a child who normally is ambulatory will help to evaluate for occult joint infection. Table 222.3 lists key symptoms and signs that should be pursued as part of the emergency evaluation of febrile infants and children.

TABLE 222.3
Key Historical and Physical Findings Relevant to the Evaluation of the Acutely Febrile Infant or Child

History

Behavior: Activity level, consolability, irritability when moved, lethargy

Hydration status: Fluid intake, urine output

Respiratory symptoms: Cough, difficulty breathing

Gastrointestinal symptoms: Vomiting, diarrhea (with blood), travel

Renal symptoms: Abdominal pain, dysuria, frequency, urgency, hematuria

Other: Focal pain (e.g., limp, sore throat, earache, abdominal pain, rash)

Medical history: Immunization status, chronic medical conditions, ill contacts

Physical examination

General appearance: Activity, eye contact, muscle tone, color, consolability

Hydration status: Mucous membranes, fontanelle, capillary refill, skin color, mottling

Respiratory: Respiratory rate, grunting, nasal flaring, rales, bronchial breath sounds, retractions

HEENT: Adenopathy, meningismus, pharyngitis, otitis media

Cardiovascular: Heart rate, murmur

Abdomen: Tenderness, guarding, organomegaly, CVA tenderness

Skin: Rash (including viral, Kawasaki disease, measles, Coxsackievirus, scarlet fever, roseola, Henoch–Schönlein purpura, varicella), petechiae

Musculoskeletal: Bone or joint tenderness, swelling, erythema, ability to ambulate

CVA, costovertebral angle.

Neonates (0 to 28 Days or Younger than 4 Weeks)

Approximately 12% to 28% of febrile neonates presenting to EDs have a serious bacterial illness (SBI) (8). Once a source such as the urinary tract is identified, neonates are at greater risk for hematogenous spread and seeding of distant sites, including the meninges. Because bacterial sepsis and meningitis can present very subtly in neonates, even the slightest changes in behavior or health (e.g., change in sleep or feeding pattern, diarrhea, or jaundice) may be indicators of significant illness. A complete septic workup, including blood and urine cultures, and lumbar puncture (LP) for cerebrospinal fluid (CSF) cultures, should be performed, and hospital admission is generally recommended (9,10). Studies have shown that implementation of a standard protocol in the ED can decrease the time to antibiotic therapy (12). Studies examining the utility of protocols that avoid performing an LP in selected neonates less than

28 days have generally been focused on ambulatory practices where follow-up is assured and contact with the PCP is well established. It has been suggested that some febrile well-appearing neonates with negative initial septic workups can be successfully managed with admission and observation without empiric antibiotic treatment, or even be discharged (13). This, however, is not a standard approach. Baker et al. in 1993, developed the Philadelphia protocol for infants between 29 and 56 days of age, but were not able to successfully apply the protocol to infants less than 28 days (13,17). In most circumstances, neonates should be treated with intravenous antibiotics until culture results are known. Ampicillin and cefotaxime are recommended as initial empiric therapy. Gentamicin can later be substituted for cefotaxime if the CSF is negative. These combinations will provide adequate coverage for the most common bacterial pathogens in this age group, including group B *Streptococcus, Listeria monocytogenes,* and *Escherichia coli.* If the infant is a recent neonatal intensive care unit graduate, the addition of vancomycin is recommended. Treatment with acyclovir for potential herpes infection should be considered for those with maternal history of herpes, vesicular rash, altered mental status, focal neurologic findings, seizures, or CSF pleocytosis with no organisms on Gram stain. In neonates less than 2 weeks of age, transaminitis and low platelet count can also be evidence of herpes infection (11).

Infants (29 to 56 Days or 4 to 8 Weeks)

Febrile infants between 4 and 8 weeks of age remain at risk for serious bacterial infections but to a slightly lesser degree than neonates. This age group continues to show only subtle manifestations of serious infection, and the physical examination continues to be of limited value. Nonetheless, there are significant bodies of evidence supporting the selective discharge of low-risk infants after a suitable ED evaluation. As a general rule, infants between 28 and 56 days should be evaluated, in the same fashion as neonates, with a complete sepsis evaluation. The differences between the Philadelphia criteria and the Boston and Rochester criteria

revolve around which patients undergo an LP and which patients are treated with empiric antibiotics.

The Philadelphia criteria was introduced in 1993 based on a prospective study of 422 infants evaluated for SBI (19). It is distinguished from the Rochester and Boston criteria primarily by not including empiric antibiotics prior to discharge (Table 222.4). This criteria (similar to the Boston protocol—see below) assumes a "well-appearing infant." It requires performing a full septic evaluation (as would be performed for a neonate 0 to 28 days); a chest x-ray is performed if clinically indicated, but a low threshold should be maintained. If the laboratory evaluation (including CSF studies) is negative, the patient may be considered low risk and may be discharged if there is guaranteed follow-up with a medical provider for reevaluation within 24 hours. The patient must remain well appearing throughout the ED stay. If at any point the patient's condition appears less than optimal, there is admission for observation, with or without antibiotics. Other issues to consider are the parents' comfort with discharge. Some parents may not feel comfortable observing the child at home and admission for observation is thus warranted. The notion of the "well-appearing infant" is therefore broader than the patient; it applies to the larger social milieu of the family and their ability to carefully monitor a potentially ill infant.

TABLE 222.4
The Philadelphia Criteria for Evaluating Young Infants with Fever

Well-appearing term infant[a] that remains well appearing through ED stay
WBC count of ≤15,000 (mm^3)
Band to neutrophil ratio of ≤0.2
Urinalysis with <10 WBC/HPF
Urinalysis with few or no bacteria on centrifuged urine specimen
CSF with <8 WBC/mm^3 with negative Gram stain
Chest radiograph negative (obtained on all patients)
Patient has guaranteed follow-up with a medical provider within 24 hrs of ED discharge for reevaluation

[a]Infant Observation Score of 10 or less.

The "Boston criteria" (Table 222.5) is also a well-validated approach to risk-stratify these young patients and is based on a study of 503 infants. The laboratory criteria differ somewhat from the Philadelphia criteria in terms of white blood cell (WBC) count (<20,000 for Boston vs. <15,000 in Philadelphia) but the evaluation includes LP, urinalysis, and blood cultures. Unlike the Philadelphia criteria, the Boston criteria require the use of empiric intramuscular ceftriaxone for infants meeting low-risk criteria prior to discharge. Follow-up for these patients involves returning to the ED in 24 hours for reassessment and a second dose of IM ceftriaxone.

TABLE 222.5
The Boston Criteria for Evaluating Young Infants with Fever

Previously healthy, nontoxic-appearing term infant
No focal infection on examination
WBC count ≤20,000 (mm^3)
CSF with ≤10 WBC/HPF
Stool WBC count ≤5 WBC/HPF when diarrhea present
Chest radiograph negative (if indicated)
Microscopic urinalysis with ≤10 WBCs/HPF or urine dipstick negative for leukocyte esterase

The "Rochester criteria" (Table 222.6) represents the earliest validated set of clinical and laboratory criteria that place infants at low risk for a bacterial infection, and allow them to be managed as outpatients (15,16). Based on these criteria, the estimated risk of

bacteremia and meningitis in low-risk infants is 1.1% and 0.5%, respectively. For children meeting the Rochester criteria, urine and blood cultures are recommended, and routine LP and empirical antimicrobials are considered optional (17,18).

TABLE 222.6
The Rochester Criteria for Evaluating Young Infants with Fever

Previously healthy, nontoxic-appearing[a] term infant
No previous antimicrobial use
No focal infection on examination
WBC count 5,000–15,000 (μL)
Band count >1,500 (μL)
Stool WBC count ≤5 WBC/HPF when diarrhea present
≤10 WBCs/HPF in spun urine

[a]Includes activity, alertness, color, strength of cry, consolability, irritability, eye contact, social responsiveness, and respiratory effort.

Which criterion to follow is driven by three factors: (1) clinician experience, (2) availability of follow-up, and (3) family comfort levels with discharge. If follow-up is likely to be challenging to accomplish or the reliability of follow-up actually taking place is in question, the Boston criteria with a dose of ceftriaxone may be preferred. This is done, however, with the understanding that the patient may not receive the second dose of ceftriaxone if they do not return for follow-up, which risks leaving a partially treated infection unfollowed. Under the vast majority of circumstances, however, reliable follow-up can be established within 24 hours, making the Philadelphia, Boston or Rochester criteria all reasonable approaches.

The key point is to select a method and stick with it. Septic evaluations should be treated as binary for less experienced clinicians, meaning that they should either be done completely or not be done at all (i.e., if the patient is not believed to have had a fever due to an infectious cause). Selective a la carte methods for testing and treatment (if any) risk missing subtle infections or can create confusion for providers who may see the patient on a subsequent visit. The role of the LP in this age group is often debated

and occasionally omitted because of parental preference, but should be considered in the context of the provider's comfort and clinical experience as well. However, the evidence that supports omitting LP from the evaluation is weak, with the possible exception of infants diagnosed with RSV bronchiolitis. In many EDs, viral testing, such as rapid tests for RSV or influenza A or B, is used to decide whether to proceed with blood, urine, and CSF studies in febrile young infants without an identified source of fever (28). The presence of a documented viral infection lowers, but does not eliminate the possibility of a coexisting serious bacterial infection. Several studies have found that febrile young infants who test positive for RSV are at low risk for bacterial infections (29,30). Those bacterial infections that do occur are predominantly urinary tract infections (UTIs), with the rate reported to be from 1.5% to as high as 5% (29,30). The studies are too small to detect differences in the prevalence of meningitis and bacteremia between RSV(+) and RSV(−) infants, but preliminary data show a trend toward lower rates in these infections as well. A number of studies found no cases of meningitis in infants who had CSF testing and who had tested positive for a viral pathogen or had clinical bronchiolitis (29,31).

Infants and Children Greater Than 8 Weeks of Age

In children older than 8 weeks of age "well appearance" becomes more reliable. Between 2 and 4 months, infants begin exhibiting a social smile, making meaningful eye contact, and starting to interact with their environment. Consequently, the contrast between "well" and "ill" becomes more apparent; linking irritability and lethargy more reliable to underlying bacterial infection.

While the evaluation of infants less than 8 weeks of age is based on screening for SBI, in children greater than 8 weeks of age the focus of diagnostic testing is on specific sources of infection such as the urine, lung, CSF and, to a lesser extent, blood. Infections arising from the skin, GI tract, and bone should also be considered under the appropriate circumstances. Table 222.7 outlines common infectious causes of fever based on the associated chief complaint. As a practical point, testing to be considered should primarily include

chest radiograph, urinalysis, and urine culture. Routine use of CBC and electrolyte testing in *well-appearing* febrile infants and children has a low yield, is invasive, and may delay patient disposition.

TABLE 222.7
Common Infectious Processes Causing Fever in Young Children and Their Associated Symptoms

Seizure
Febrile seizure
Meningitis
Encephalitis

Headache[a]
Meningitis
Encephalitis
Sinusitits

Ear Pain
Otitis media
Otitis externa
Mastoiditis

Sore Throat
Pharyngitis/tonsillitis
Gingivostomatitis
Coxsackievirus "hand-foot-and-mouth disease"
Parotitis (viral or suppurative)
Tonsillar/pharyngeal abscess (uncommon)
Peritonsillar cellulitis/abscess (uncommon)

Face or Neck Pain
Periorbital cellulitis
Orbital cellulitis
Facial cellulitis
Cervical adenitis

Rhinorrhea
Common cold/influenza
Sinusitis

Stridor
Croup
Epiglottitis (uncommon)

Cough
Pneumonia
Bronchiolitis
Bronchitis

Chest Pain or Palpitations
Myocarditis (uncommon)
Endocarditis (uncommon)

Abdominal or Pelvic Pain and/or Vomiting
Acute gastroenteritis
Appendicitis
Acute salpingitis
Epididymitis

Dysuria
Urinary tract infection

Joint Pain
Toxic synovitis
Septic arthritis
Osteomyelitis

Rash
Viral exanthem
Roseola infantum
Meningococcemia

Systemic
Bacterial sepsis/bacteremia
Viremia
Rocky Mountain spotted fever
Toxic shock syndrome

[a]Elevated body temperature alone is a common cause of headache. Symptoms should improve with the use of an antipyretic and lowering of the elevated body temperature.

Fever may be the only indication of a UTI in a young child. Up to 7% of febrile young children in whom no source is identified on physical examination have a UTI. In one study, up to 4% of young

febrile children younger than 2 years old who were found to have either acute otitis media or gastroenteritis as a source for fever, also had a UTI (20). A urinalysis and culture is recommended as part of the workup of girls younger than 2 years old, of circumcised boys up to 6 months of age, and of uncircumcised boys up to 12 months. A dipstick and microscopic urinalysis are insufficiently accurate to be used alone to evaluate the presence of UTI in young children and, a urine culture should be ordered as well (21). Enhanced urinalysis, defined as including either a Gram stain or cell count by hemocytometer, has a higher sensitivity and specificity than standard urinalysis for the diagnosis of a UTI; however, this type of testing is not available in all locations (21). (See Chapter 288.)

Pneumonia is rarely present without clinical signs of lower respiratory tract disease (22). Indications for a chest x-ray include tachypnea, retractions, nasal flaring, abnormal auscultatory findings, or a pulse oximeter reading of $<92\%$ (22). Occasionally, occult pneumonia may present only as abdominal pain and fever. (See Chapter 265.)

When no source for a fever is found on physical examination and pneumonia and UTI have been excluded by physical examination and laboratory tests, the possibility of occult bacteremia should be considered. Occult bacteremia is a concern because there is a potential for seeding other areas, and sequelae such as pneumonia, septic arthritis, and meningitis.

Since the late 1980s, three new childhood vaccines (HiB) and two pneumococcal vaccines (PCV-7 and PCV-13) have greatly reduced the incidence of serious bacterial infections, including occult bacteremia, due to these pathogens, and have changed our approach to the young child with significant fever and no apparent source (23,24). Before the advent of these vaccines, the incidence of occult bacteremia rate was 3% to 5%, and even higher in patients with an elevated WBC count or very high temperatures ($>40^{\circ}C$, $104^{\circ}F$). Management included blood cultures and empiric antibiotics until the results of blood cultures were known. Currently, there is increasing evidence that the incidence of bacteremia, and specifically the rate of pneumococcal bacteremia, has decreased to the point that

using testing and empiric treatment may no longer be justified (5,12,23,28).

In an otherwise healthy, well-appearing, febrile young infant or child with just two sets of the HiB and pneumococcal vaccines, blood cultures and empiric antibiotics are not recommended (25). For children with one or no vaccines against these organisms, occult bacteremia must be considered. But even for these "unprotected" febrile infants, lower rates of pneumococcal bacteremia are seen due to "herd" immunity (26).

Biomarkers such as the WBC count, absolute neutrophil count (ANC), and the C-reactive protein (CRP) have long been used to evaluate well-appearing febrile children without an obvious source of infection for the risk of occult infection such as bacteremia. Although of less utility because of the current very low rate of occult bacteremia, CRP appears to be more sensitive than the white count in identifying occult bacteremia and other serious bacterial infections. Procalcitonin appears to have approximately the same performance characteristics as CRP, but may be more sensitive in children who present within the first 6 to 8 hours of fever onset (27).

The decision to consider occult bacteremia also depends on the physician's experience, the infant's birth and past medical history, the prevalence of viral disease in the family or community, the duration of illness, and the family's ability to obtain follow-up.

KEY TESTING

Neonates (0 to 28 Days or Younger than 4 Weeks)

- Complete sepsis evaluation including LP, CBC, electrolytes, urinalysis, blood cultures, and urine cultures

Infants (29 to 60 Days or 4 to 8 Weeks)

- Complete sepsis evaluation including LP, CBC, electrolytes, urinalysis, blood cultures, and urine cultures guided by risk-stratification protocols*

Infants and Children Greater than 8 Weeks of Age

- Urinanalysis if indicated by history and degree of fever (see Chapter 288)

- Chest x-ray if indicated by history and presentation (see Chapter 265)

*Philadelphia, Boston and Rochester protocols.

CRITICAL INTERVENTIONS

- In febrile infants younger than 1 month of age, perform a complete evaluation for the source of the fever, including LP, and administer antibiotics.
- In febrile infants 1 to 2 months of age, perform a complete evaluation for the source of the fever. If empiric antibiotics are to be prescribed, an LP should be done prior to their administration.
- For ill-appearing or immunocompromised febrile infants and children, perform aggressive resuscitation and evaluation for the source of the fever and promptly initiate antibiotic treatment.
- Undress all febrile children: Petechiae may be an early indication of meningococcal disease.

DISPOSITION

Fever control with acetaminophen (15 mg/kg every 4 to 6 hours) or ibuprofen (10 mg/kg every 6 hours); cool, clear liquids; and light clothing are advised. The alternating administration of acetaminophen and ibuprofen for the management of fever is sometimes advocated by parents and health care providers, but no strong evidence supports this practice (32).

Although experimental evidence suggests that fever may be adaptive and stimulate the immune system, fever reduction has not proven to be deleterious and does lead to increased patient comfort and decreased metabolic demands and fluid loss. Control of fever is thus recommended.

Discharge instructions for febrile children should include indications for urgent return (Table 222.8). The most important indications for urgent reevaluation are lethargy and persistent irritability. Even with continued fever, if the child's behavior and disposition improve, urgent reevaluation is unnecessary. A child

younger than 2 months old or a child who has been given empiric antibiotics must be followed up in 12 to 24 hours by a primary care physician or other medical provider.

Pain

Common Pitfalls

- Failing to carefully evaluate and document the child's general appearance.
- Failing to account for an infant's age in determining the extent of the fever evaluation.
- Overrelying on acute-phase reactants such as the WBC count or ANC instead of clinical assessment and observation.
- Failing to consider noninfectious disease processes as a cause for fever.

CHAPTER 223 Vomiting

Ronald A. Furnival and Marissa A. Hendrickson

Vomiting is the coordinated action of the pharyngeal, esophageal, stomach, and diaphragmatic musculature to expel gastric contents, directed by the medullary vomiting center within the central nervous system. This center receives input from the chemoreceptor trigger zone in the floor of the fourth ventricle and from higher cortical centers that receive and process external stimuli. Although vomiting may provide a survival advantage by expelling ingested toxins, it frequently occurs with disorders from a variety of organ systems (1).

Infants and children with vomiting commonly present to the emergency department (ED) for diagnosis and treatment. For most pediatric patients, vomiting is associated with relatively minor self-limited conditions, but it may also be a manifestation of serious surgical or medical illness. In the ED, the first priority must be to determine whether clinical stabilization is immediately required and whether an emergent surgical or medical condition exists. If no evidence of serious illness is identified, the next priority becomes recognizing and initiating therapy for the less urgent clinical conditions associated with vomiting.

CLINICAL PRESENTATION

The initial ED history and physical examination should identify and address any evidence of systemic illness or toxicity. Persistent vomiting with severe dehydration or metabolic abnormalities may require treatment prior to establishing a definitive diagnosis. Because pediatric vomiting may be a nonspecific symptom associated with severe systemic illness (e.g., meningitis, sepsis, respiratory distress,

drug overdose, closed head injury, ventriculoperitoneal shunt failure, etc.), the ED evaluation must consider or rule out these possible etiologies, based upon the initial history and physical examination.

The initial history must define whether the emesis is bilious or nonbilious. Bilious vomiting, containing dark green material from the biliary tract, generally indicates a mechanical or functional bowel obstruction below the ampulla of Vater. Nonbilious emesis implies either a more proximal obstruction in the duodenum or a functional disorder with no mechanical bowel obstruction (1). Yellow bile-stained emesis occasionally may occur with persistent vomiting and no bowel obstruction. This emesis is usually caused by a temporary reversal of gastric peristalsis. Fecal material in the emesis indicates a colonic obstruction, as in severe obstipation, Hirschsprung disease, or other large bowel disorders. Although studies have found that only 10% to 38% of infants and children presenting to the ED with bilious (either yellow or green) vomiting will ultimately be diagnosed with an emergent surgical condition, every child with bilious emesis must be assumed to have a bowel obstruction until proven otherwise (2–4).

The duration of vomiting, the number of episodes each day, and any additional gastrointestinal (GI) symptoms should be defined next, including abdominal pain, distention, anorexia, diarrhea, constipation, and presence of blood in the emesis or stools. The history should also note presence of systemic (fever, weight loss, nutritional status, hydration status), neurologic (headache, neck pain or stiffness, coordination or behavioral changes), genitourinary (dysuria, hematuria, change in urine output, vaginal discharge or bleeding), respiratory (cough, evidence of distress), or head and neck (otalgia, sore throat, dysphagia, nasal drainage) symptoms to further direct care and diagnostic evaluation. A past history of similar severe episodes of vomiting may lead to the diagnosis of a recurring condition, such as cyclic vomiting, an inborn error of metabolism, or malrotation with intermittent volvulus; a history of early morning vomiting should raise concerns for an intracranial mass lesion (1).

The physical examination should initially seek evidence of systemic toxicity, including respiratory or cardiovascular instability,

altered mental status, or severe dehydration. A validated pediatric scoring tool for the clinical assessment of dehydration using a combination of four objective physical findings (dry mucous membranes, absent tears, abnormally lethargic or restless appearance, prolonged capillary refill) has proven to be helpful in the recognition of dehydration, with two of four findings present with 5% dehydration, and three or more present with more severe states of dehydration (5–7).

On abdominal examination, auscultation for bowel sounds prior to palpation may reveal diminished activity with ileus arising from surgical or medical illness, or increased activity (borborygmi) with partial bowel obstruction or a diarrheal disorder. Next, palpation for abdominal tenderness, distention, mass, or enlargement of the liver or spleen should be performed. Gentle one- or two-finger percussion, rather than the less accurate gross abdominal wall movement with the compression-rebound technique, may demonstrate peritoneal findings associated with surgical conditions such as appendicitis. Finally, a thorough general evaluation for nonabdominal conditions associated with vomiting, including the head and neck, pulmonary, genitourinary, and neurologic examination, may identify the etiology and direct or obviate further diagnostic workup.

DIFFERENTIAL DIAGNOSIS

While viral gastroenteritis is one of the most common causes of vomiting for infants and children of all ages, the differential diagnosis for vomiting varies according to age at presentation. Table 223.1 outlines an age-based differential diagnosis for surgical and medical etiologies of pediatric vomiting.

TABLE 223.1
Age-Based Differential Diagnosis for Vomiting

All Ages

Surgical

- Appendicitis
- Bowel obstruction (adhesions from previous surgery)
- Malrotation with intermittent volvulus
- Incarcerated inguinal hernia
- Closed head trauma (accidental or abuse)
- Abdominal trauma (accidental or abuse)
- Ventricular peritoneal shunt failure

Medical

- Generalized sepsis
- Meningitis, encephalitis
- Hepatitis
- Toxin ingestion/drug overdose
- Urinary tract infection
- Viral or bacterial gastroenteritis

Infant

Surgical

- Pyloric stenosis
- Congenital GI anomalies (intestinal stenosis or duplication, duodenal or antral webs, annular pancreas, etc.)
- Malrotation with volvulus
- Hirschsprung disease
- Intussusception
- Necrotizing enterocolitis

Medical

- Gastroesophageal reflux
- Head and neck (upper respiratory infections, sinusitis, otitis media, pharyngitis, stomatitis)
- Respiratory distress (bronchiolitis, pneumonia, asthma, pertussis, aspiration in the developmentally impaired)
- Viral or bacterial gastroenteritis
- Urinary tract infection
- Metabolic conditions (inborn errors of metabolism, renal tubular acidosis, congenital adrenal hyperplasia)

Child

Surgical

- Appendicitis
- Intussusception
- Cholecystitis
- Intracranial (occult closed head injury, abuse, hydrocephalus, mass, hemorrhage)

Medical

- Viral or bacterial gastroenteritis
- Metabolic (type 1 diabetes, diabetic ketoacidosis)
- Renal (insufficiency, ureteropelvic junction obstruction, nephrolithiasis)
- Adrenal insufficiency
- Henoch–Schönlein purpura
- Drug/toxin accidental ingestion
- Pancreatitis
- Urinary tract infection
- Inflammatory bowel disease
- Neurologic (migraine headaches, seizure variants)
- Cyclic vomiting
- Peptic ulcer disease

Adolescent

Surgical

- Appendicitis
- Ovarian (torsion, cysts)
- Cholecystitis

Medical

- Pregnancy (ectopic or intrauterine)
- Pelvic inflammatory disease
- Drug/toxin overdose
- Viral or bacterial gastroenteritis
- Metabolic (type 1 diabetes, diabetic ketoacidosis)
- Renal (insufficiency, ureteropelvic junction obstruction, nephrolithiasis)
- Adrenal insufficiency
- Pancreatitis
- Urinary tract infection
- Inflammatory bowel disease
- Neurologic (migraine headaches, seizure variants)
- Cyclic vomiting
- Peptic ulcer disease

For the infant from birth to 2 months of age, the most common condition associated with vomiting is gastroesophageal reflux, often resulting from overfeeding; it typically occurs within 30 to 60 minutes of feeding in an otherwise healthy-appearing infant. Occult gastroesophageal reflux may present as positional fussiness, persistent cough and congestion, or truncal arching (Sandifer syndrome) that may mimic tonic seizure activity. Reflux precautions, including formula thickened with rice cereal, small frequent feedings, and upright positioning for 30 minutes after feedings, will effectively treat the majority of infants. Persistent reflux may require medical therapy (8).

Pyloric stenosis is the most common surgical condition that must be differentiated from gastroesophageal reflux in vomiting infants.

Most affected infants present at 3 to 4 weeks of age, with a history of 1 to 2 weeks of progressive forceful “projectile” nonbilious vomiting. With more advanced disease, there may be weight loss from severe dehydration. While palpation of the hypertrophied pylorus or “olive” is diagnostic, the physical examination is often nonspecific, and an ultrasound is generally required for definitive diagnosis in younger infants (9,10). ED treatment includes prompt evaluation for electrolyte disturbances (the classic presentation with hypochloremic metabolic alkalosis has become increasingly rare) and intravenous (IV) fluid rehydration, with surgical referral for suspected cases (9).

Other emergent surgical causes of vomiting in the first 2 months of life include congenital GI anomalies (intestinal stenosis or duplications, duodenal or antral webs, annular pancreas, etc.), incarcerated inguinal hernia, malrotation with volvulus, and Hirschsprung disease. Most UGI congenital anomalies present within the first few days of life and are infrequently seen in the ED setting. An inguinal hernia may be noted on examination of the diaper area, with the presence of an inguinal, scrotal, or labial mass. Steady and gentle pressure at the external inguinal ring and on the mass can successfully reduce the majority of hernias. However, some patients may require sedation and surgical consultation if the initial ED attempt is unsuccessful.

The young infant presenting to the ED with bilious emesis (even one episode) must, without exception, be assumed to have GI malrotation with volvulus until proven otherwise. Eighty-five percent of patients with volvulus present in the first year of life, and 60% of patients present within the first month of life. The abdominal examination may be normal in up to 75% of cases, but diminished bowel sounds, distention, a palpable mass, or tenderness may be noted in 10% to 25% of infants with volvulus (3). Hypovolemic shock from prolonged intestinal ischemia is uncommon at presentation, but must be considered in the moribund infant. Immediate evaluation with a UGI series (a contrast enema may miss the diagnosis in up to 20% of patients) is required for all suspected cases, with emergent surgical consultation and laparotomy for any symptomatic patient with an identified malrotation (1,3,11).

Hirschsprung disease, or aganglionosis, is a fairly common cause of intestinal obstruction in newborns, infants, or young children. It occurs in 1 in 5,000 live births, and more than 80% of cases are diagnosed within the first year of life. Up to 90% of infants with Hirschsprung disease have a history of failure to pass meconium in the first 24 hours of life, making this an important historical question for any child presenting with abdominal pain. Hirschsprung is due to a congenital absence of ganglion cells in the colonic submucosa, resulting in uncoordinated intestinal contractions which manifest clinically as chronic constipation, abdominal distention, and vomiting. Abdominal radiographs may demonstrate dilated proximal bowel loops with air-fluid levels; a contrast enema may be diagnostic in more than 80% of cases. ED treatment consists of IV fluid resuscitation, nasogastric (NG) decompression, broad-spectrum antibiotics (with anaerobic coverage), and surgical consultation for confirmatory biopsy and corrective surgery (12). Even after corrective surgery, toxic megacolon or enterocolitis remains a significant concern, occurring in more than one-third of Hirschsprung patients because of retained aganglionic segments of bowel. Enterocolitis may present as abdominal distention, foul watery diarrhea, lethargy, or systemic toxicity, and must be recognized and treated early with aggressive supportive care, including broad-spectrum antibiotics and rectal irrigation (12).

Many other medical conditions may cause vomiting in young infants. Infections such as sepsis, meningitis, encephalitis, hepatitis, pharyngitis, stomatitis, or otitis media may present with vomiting as an initial symptom. Gastroenteritis is common year-round, with seasonal peaks during summer and winter viral outbreaks. Urinary tract infection is the most common bacterial source for a fever in infants with a normal physical examination, and may present with vomiting and no diarrhea (13). Respiratory distress from pertussis, pneumonia, asthma, bronchiolitis, or aspiration in the developmentally impaired patient may also be noticed only after the infant has been vomiting.

Intracranial pathology, from occult closed head injury, abuse, hydrocephalus, or hemorrhage may present with neurologic findings

and associated vomiting. Victims of nonaccidental trauma involving occult head trauma or abdominal trauma may present with vomiting. Only with careful history taking and consideration of abuse as an etiology will these cases be detected (see Chapter 290). Patients with indwelling ventricular peritoneal shunts (see Chapter 291) may present with vomiting as their only sign of increasing intracranial pressure (ICP) with shunt failure.

Finally, metabolic conditions such as inborn errors of metabolism, renal tubular acidosis, and congenital adrenal hyperplasia may present as vomiting with metabolic acidosis, hypoglycemia, hyperammonemia, or hyperkalemia in combination with hyponatremia (14,15). While a number of the conditions outlined previously may also affect the older infant or child, gastroesophageal reflux, congenital anomalies, and inborn metabolic disorders become less likely with increasing age.

Two common surgical disorders to consider in the older infant or child with vomiting are appendicitis and intussusception. While only 10% of appendicitis occurs in children younger than 10 years of age, and only 1% in infants younger than 2 years, it remains the most frequent indication for emergent pediatric surgery. The “classic” findings of right lower quadrant abdominal pain, vomiting, and fever are uncommon in younger patients, who may have an atypical history of diarrhea or respiratory distress, evidence of generalized sepsis, or atypical laboratory findings at presentation (16). Because of the nonspecific nature of such symptoms and perhaps a more rapid progression to perforation, appendicitis in the child younger than 4 years of age is often associated with an 80% perforation rate at the time of diagnosis and a significant mortality risk among younger infants. Older children may be more likely to have the classic presentation of appendicitis, and may be appropriate for surgical consultation and clinical diagnosis.

While contrast pelvic computed tomography (CT) scan has been quite accurate for the diagnosis of pediatric appendicitis, recent research has attempted to improve appendicitis diagnostic accuracy, while limiting CT scan utilization and its associated radiation risk. A multicenter-validated prediction rule using an absolute neutrophil

count $\leq 6.75 \times 103$ μL with either no maximal tenderness in the right lower abdominal quadrant, or absence of pain with walking or jumping, was able to identify children at low risk of appendicitis with 98% sensitivity, patients who may be appropriate for further clinical observation (17). If imaging is utilized for the diagnosis of appendicitis, a staged approach using US, followed by CT scan if negative or equivocal, has been found to be both very sensitive for the diagnosis, and cost-effective, while limiting radiation exposure (18,19).

Intussusception, from a spontaneous invagination of the intestine upon itself, compromises the vascular supply to the inner segment or intussusceptum. Approximately 95% of intussusception is ileocolic, beginning at the ileocecal valve; the remaining 5% are ileoileal or occur within the colon or sigmoid. Sixty-five percent of intussusception occurs in infants younger than 1 year of age, most frequently (45%) between 5 and 9 months of age (20). The typical infant presents with sudden onset of intermittent severe abdominal pain and vomiting and may appear well between episodes. Bilious vomiting, lethargy, passage of bloody mucus or "currant-jelly" stool, peritonitis, or evidence of cardiovascular compromise are often late findings that indicate more advanced intestinal ischemia, which may require surgical resection (21). The abdominal examination may identify a palpable mass but is usually normal, often with only a positive stool guaiac test to confirm the clinical suspicion for intussusception; abdominal radiographs are generally normal or nonspecific (22). Ultrasound or air-contrast enema is diagnostic for nearly 100% of cases. Air-contrast enema allows therapeutic reduction of the intussusception, and is associated with successful reduction in up to 90% of pediatric cases (23).

In older infants and children, vomiting may be due to a number of medical conditions, including endocrinologic disorders such as new-onset type 1 diabetes, which may present as diabetic ketoacidosis, or renal and adrenal insufficiency. Henoch–Schönlein purpura (HSP), with its characteristic vasculitic lesions concentrated on the lower extremities, may cause abdominal pain and vomiting associated with HSP's increased risk for intussusception.

A number of other conditions, both common and uncommon, may also need to be considered. In accidental drug ingestion in the exploring toddler or intentional overdose in the adolescent, vomiting may be associated with toxin-specific findings. Pancreatitis, cholecystitis, inflammatory bowel disease, and nephrolithiasis, most often seen in older patients, may also present with frequent vomiting. Migraine, cyclic vomiting, and some seizure variants may cause recurrent vomiting episodes (24). Pregnancy (intrauterine and ectopic), ovarian cysts, torsion, and pelvic inflammatory disease must be considered in the differential of the vomiting adolescent female.

DIAGNOSTIC APPROACH

The initial ED therapy for the vomiting infant or child must focus on identifying and managing any evidence of systemic toxicity. Patients with clinical evidence or concern for increased ICP or occult abdominal injury should be stabilized and imaged emergently. Most well-appearing or mildly ill-appearing children without severe abdominal pain, bilious vomiting, or evidence of medical or surgical emergency can be managed with a trial of oral hydration with clear liquids, facilitated with oral ondansetron. However, in children with evidence of clinical instability, prompt IV access should be established, with fluid administration of 20 mL/kg boluses of isotonic normal saline or lactated Ringers solution, and repeated boluses as needed. Analgesics should be administered early in the child being evaluated for appendicitis or other painful conditions; well-designed prospective pediatric studies have found no adverse effects of ED pain control on diagnostic accuracy or clinical outcomes (25). Surgical consultation should be arranged for all patients with suspected surgical conditions, evidence of peritonitis, or unstable trauma prior to reaching a definitive diagnosis.

Initial diagnostic laboratory studies generally include serum electrolytes, glucose, and renal function tests when there is clinical evidence of moderate to severe dehydration. A bedside glucose measurement should be obtained in unstable patients with altered mental status or in whom undiagnosed diabetes is in the differential

diagnosis. In the mildly dehydrated child the bedside glucose may be the only test needed. Additional tests may also be indicated for more severely ill children including a complete blood count (CBC) with a type and cross-match for surgical patients, liver function tests, lipase test for undiagnosed pancreatitis or gall bladder disease, and a urinalysis and urine culture for the febrile patient with a possible urinary tract infection.

After initial stabilization, diagnostic imaging may be necessary to identify the cause of vomiting. A chest x-ray should be considered in the patient with respiratory symptoms and may lead to the diagnosis of pneumonia. If the infant or child is suspected of having bowel obstruction, ileus, or mass, or with evidence of peritonitis, flat and upright abdominal x-rays may confirm the diagnosis and direct further care. For the young infant with bilious vomiting, the initial test of choice is unquestionably the UGI series, which is more sensitive for the diagnosis of malrotation than contrast enema studies. However, confirmatory studies must not delay an emergent surgical consultation in this situation. The contrast enema may be both diagnostic and therapeutic for the older infant or toddler with a suspected intussusception, although ultrasound is often the preferred initial diagnostic test. A contrast enema may also diagnose Hirschsprung disease in the infant with chronic constipation, demonstrating a funnel-shaped transition zone at the border between the normal and abnormal bowel segments. Ultrasound is often helpful in diagnosing pyloric stenosis, appendicitis, intussusception, ureteropelvic junction obstruction, and gynecologic disorders. Appendicitis may be diagnosed by ultrasound or a pelvic CT scan, though a staged approach with an initial US is recommended to minimize the radiation exposure associated with CT (18,19). CT scan is, however, the test of choice for the evaluation of abdominal masses, nephrolithiasis, abdominal trauma, and intracranial pathology.

CRITICAL INTERVENTIONS

- Address clinical instability prior to efforts at definitive diagnosis.

- Check a bedside serum glucose in the infant or child with altered mental status or other evidence of systemic toxicity.
- Give stress-dose corticosteroids (hydrocortisone 25–100 mg IV bolus) to the ill-appearing steroid-dependent patient as soon as possible.
- Consider bilious vomiting or evidence of peritonitis to be caused by an emergent surgical condition until proven otherwise.

DISPOSITION

For the vomiting infant or child with a self-limited condition, no evidence of serious systemic illness, and only mild or moderate dehydration, ED oral hydration with continued outpatient oral rehydration is appropriate, along with defined discharge instructions and a clear follow-up plan. IV fluid rehydration should be utilized for the vomiting patient who cannot tolerate oral fluids, with demonstrated electrolyte abnormalities, or with more severe illness. Recent well-designed prospective pediatric studies have demonstrated a benefit from the administration of oral or IV ondansetron with ED rehydration, noting a significant reduction in continued vomiting, improved tolerance of oral fluid challenges, and reduced hospital admission rates (26–28). While two 20 mL/kg IV isotonic fluid boluses may improve most mildly dehydrated patients enough to make them safe for discharge, those with persistent vomiting, and significant serum electrolyte or glucose abnormalities may benefit from continued inpatient rehydration and observation.

Common Pitfalls

- Overzealous use of laboratory studies and IV fluids in well-appearing children with vomiting; many can be managed with oral hydration and oral ondansetron as needed.
- Forgetting to assess for hypoglycemia in a vomiting infant or child. A rapid glucose test should be checked with the first blood draw.
- Failing to aggressively evaluate and treat the young infant with bilious emesis, even if physical examination and laboratory

studies appear normal. Do not miss the diagnosis of malrotation.
- Overlooking subtle presentations of occult injury in patients with nonaccidental trauma, accidental or intentional ingestions, and ventriculoperitoneal shunt failures.

CHAPTER 224
Diarrhea

Jeahan H. Colletti and James E. Colletti

Diarrheal illness continues to be a significant cause of pediatric morbidity and mortality. Worldwide diarrheal illnesses are the second leading cause of mortality in children under 5 years of age, accounting for approximately 1.5 million deaths per year (1).

CLINICAL PRESENTATION

The most common presenting etiology of diarrhea in children is infectious gastroenteritis, with viral agents accounting for 75% of cases. Acute diarrhea typically lasts less than 2 weeks, and the history is one of a distinct change in stool frequency, volume, and color. The stools may be less well-formed and yellowish, loose and green, or watery and voluminous. The presence of bloody, mucoid stools increases the possibility of a bacterial cause. Vomiting is common, especially with viral disorders. However, bilious vomiting requires close attention and raises the possibility of intestinal obstruction. Intussusception may complicate an otherwise mild gastroenteritis. Low-grade fever is common, but fever in excess of 40°C suggests a bacterial etiology.

Important history includes antibiotic use, recent travel, or other exposures such as daycare, pets, or an unsanitary water supply. The patient's prior weight, duration of illness, and associated signs and symptoms, such as fever, abdominal pain, vomiting, rash, seizures, and activity level, can aid in determining the degree and severity of dehydration. A vital component of the history is the type of oral intake given to the child. The use of hyperosmolar fluids, such as carbonated soft drinks, apple juice, or excess sodium due to improper

formula preparation, can result in hypernatremia, whereas hypotonic fluid replacement can result in hyponatremia.

Assessment for signs of dehydration is of vital importance Infants may become critically dehydrated over a period of only a few hours and present with shock. As the vascular space contracts, the extremities become cool with decreased distal pulses, and alterations in mental status occur. Gorelick et al. (2) discovered that the findings of three or fewer of the clinical signs of dehydration correlated with a 5% fluid deficit, three to five signs correlated with 5% to 9% dehydration, and more than six signs with a fluid deficit of 10% or greater. In general, the diagnosis of dehydration is improved by the presence of multiple signs or through the use of clinical scales.

Parental reporting has been found to accurately predict degree of dehydration as well as clinically significant acidosis (3). A parental report of a normal tearing state is associated with a reduced likelihood of significant dehydration and acidosis. Moreover, parental reporting of a sunken fontanelle and decreased tears are associated with an increased likelihood of hospital admission (3).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of diarrheal illness is broad. Diarrhea may accompany almost any pediatric illness at any given point in its course. The differential diagnosis may be categorized as acute or chronic. There may be important diagnostic clues based on the child's age, character of the stool, associated symptoms, and effect on the child's general health.

The most common causes of acute and chronic diarrheal disease are listed in Table 224.1. The vast majority of acute diarrheal illnesses are viral. Before the introduction of the rotavirus vaccines, rotavirus was the leading cause of severe acute gastroenteritis (AGE) in US children less than 5 years of age. Since the introduction of the vaccines in 2006, there has been a significant (60% to 65%) reduction in the number of rotavirus-associated hospitalizations (4). With the reduction in rotavirus-associated diarrhea, the Noroviruses have become the leading cause of AGE in children.

TABLE 224.1
Common Causes of Acute and Chronic Diarrheal Illness

Common Causes of Acute Diarrheal Illness	Causes of Chronic Diarrheal Illness
Bacterial	
Campylobacter	Urinary tract infection
Salmonella	
Shigella	
Yersinia	
Escherichia coli	
Clostridium perfringens	
Clostridium botulinum	
Clostridium difficile	
Cholera	
Staphylococcus aureus	
Aeromonas	
Viral	
Rotavirus	
Norwalk virus	
Adenovirus	
Calicivirus	
Astrovirus	
Torovirus	
Parasitic	
Giardia lamblia	*Giardia lamblia*
Cryptosporidium	
Entamoeba histolytica	
Other	
Medication-induced	Postinfectious disaccharide intolerance
Parenteral: otitis media, upper-respiratory infection, urinary tract infection	Irritable bowel syndrome
Food intolerance	Milk or soy protein intolerance
Psychogenic: anxiety	Food allergy
Necrotizing enterocolitis	Maternal deprivation syndrome
Cystic fibrosis	Cystic fibrosis
Adrenal insufficiency	Celiac disease
Organophosphates	Immunodeficiency disorders
Heavy metals (iron)	Short bowel syndrome (postoperative)
Hirschsprung disease	Inflammatory bowel disease
Intussusception	Tumors (neuroblastoma, carcinoid)
	Stagnant loop syndrome
	Acrodermatitis enteropathica
	Adrenal insufficiency or hyperthyroidism
	Chronic constipation with overflow diarrhea

ED EVALUATION AND MANAGEMENT

The goals of diarrhea management include prevention of dehydration by early fluid administration, treatment of dehydration with an oral rehydration solution (ORS), continued feeding during the diarrhea, selective use of antibiotics, and avoidance of antidiarrheal medications (5,6).

A thorough history should determine acute or chronic status. Preliminary studies that may be indicated for chronic diarrhea include a stool examination for blood, parasites, culture, Sudan fat stain, and alpha-1-antitrypsin. If there is significant dehydration or failure to thrive, the child should be hospitalized. Otherwise, the patient should be referred to a pediatrician for further evaluation.

If the diarrhea is acute, the primary concern is for dehydration, acidosis, electrolyte disturbances, shock, or associated sepsis. The physical examination indicates the degree of dehydration (Table 224.2). The serum bicarbonate level may occasionally also prove useful. A bicarbonate concentration of <17 mEq/L, when considered along with clinical parameters may improve accuracy in determining the presence of moderate to severe dehydration (7,8). Conversely, a bicarbonate concentration of >15 or 17 mEq/L decreases the likelihood of dehydration (9). Furthermore, a bicarbonate of ≤ 13 mEq/L is associated with a need for prolonged IV fluid replacement (3,10). Other than a guaiac test or culture, stool studies such as fecal leukocytes, Rotazyme, pH, reducing substances, and ova and parasites are usually not helpful in the emergent setting.

TABLE 224.2
Estimating Degree of Dehydration

Symptom	Minimal or No Dehydration (<3% Loss of Body Weight)	Mild to Moderate Dehydration (3%–9% Loss of Body Weight)	Severe Dehydration (>9% Loss of Body Weight)
Eyes	Normal	Sunken slightly	Sunken deeply
Tears	Present	Diminished	Absent
Mouth and tongue	Moist	Dry	Parched
Thirst	Drinks normally	Eager to drink	Drinks poorly; unable to drink
Heart rate	Normal	Normal to increased	Tachycardia, with bradycardia in most severe cases
Quality of pulses	Normal	Normal to decreased	Weak, thready, or impalpable
Extremities	Warm and well perfused	Cool	Cold; mottled; cyanotic
Capillary Refill	Normal	Prolonged	Minimal
Respiration	Normal	Normal to fast	Deep
Skin fold	Recoils instantly	Recoil in less than 2 sec	Recoil in greater than 2 sec
Level of alertness	Alert	Normal to fatigued or restless, irritable	Lethargic, unconscious
Urine output	Normal to decreased	Decreased	Minimal

Available online at http://www.who.int/child-adolescent-health/New_Publications/CHILD_HEALTH/WHO.CDR.95.3.htm; Colletti JE, Brown KM, Sharieff GQ, et al. The mangement of children with gastroenteritis and dehydration in the emergency department. *J Emerg Med*. 2010;38(5):688–698.

KEY TESTING

- Well-appearing child with minimal or no dehydration—no testing
- Ill-appearing child or signs of significant dehydration—electrolytes (serum bicarbonate and glucose levels of particular interest)
- Febrile child with bloody stools—stool culture

Dehydration exceeding 5% to 10%, or significant electrolyte disturbances, are considerations for admission. Rehydration should begin in the emergency department (ED). In children who are mildly to moderately dehydrated and refusing oral intake, a nasogastric tube can be placed to initiate replacement therapy. An investigation by Nager and Wang (11) examined rapid nasogastric hydration and rapid intravenous hydration and determined them to be safe, efficacious, and cost-effective alternatives to standard therapy for moderately dehydrated children. When rapid nasogastric hydration was compared to rapid intravenous hydration, there was no significant difference. In this trial, rapid nasogastric hydration was achieved by administering a continuous infusion of 50 mL/kg of Pedialyte over 3 hours, and rapid intravenous hydration was performed by a continuous infusion of 50 mL/kg of normal saline over 3 hours.

In severely dehydrated children, intravenous normal saline boluses of 20 cc/kg should be initiated, with repeat boluses as needed to restore intravascular volume. It is common to administer 60 to 80

cc/kg in the initial phase of fluid resuscitation. Close monitoring of the pulmonary status and urine output is important in children with underlying cardiac or pulmonary conditions. Once intravascular volume has been restored, dextrose-containing maintenance fluid should be initiated. Potassium replacement should continue until the patient is spontaneously voiding and is known to have normal renal function.

In mild to moderate dehydration, oral rehydration therapy (ORT) should begin with a commercially available ORS. ORT is an inexpensive, effective therapy for dehydration that is underutilized in the United States (12). In mildly to moderately dehydrated children, ORT is as effective as IV therapy. Furthermore, ORT has been found to be associated with higher parental satisfaction and decreases in both length of stay and staff time (6,12).

Homemade solutions and electrolyte-glucose beverages for athletes should be avoided the former because serious errors may be made in preparation and the latter because they contain too little sodium, too much sugar, and almost no potassium. The use of carbonated beverages, apple juice, and Jello water should also be discouraged, as they consist of high concentrations of carbohydrates and low concentrations of required electrolytes. The high osmotic load of these fluids often results in an *increase* in stool output, and their low sodium content may contribute to hyponatremia (13,14). Each liter of a commercial ORS contains about 45 to 75 mEq sodium, 20 to 25 mEq potassium, 2% glucose, and a mixture of chloride and base as anions (Table 224.3). This ratio of electrolytes and glucose promotes the coupled mucosal transport of sodium and glucose, with water absorption following.

TABLE 224.3
Contents of Commercial Oral Rehydration Solutions

Solution	Na (mEq/L)	K (mEq/L)	Other (mEq/L)	Cl (mEq/L)	Base (mEq/L)	Carbohydrate (g/L)
Pedialyte	45	20	—	35	30	25
Rehydralyte	75	20	—	65	30	25
Infalyte	50	25	—	45	34	30
Resol	50	20	8	50	34	20
WHO solution	90	20	—	80	30	20

Adapted from Stone B. Fluids and electrolytes. In: Robertson J, Shilkofski N, eds. *The Johns Hopkins Hospital: The Harriet Lane Handbook*. 17th ed. Philadelphia, PA: Mosby; 2005. King CK, Glass R, Bresee JS, Duggan C. Managing acute gastroenteritis among children: Oral rehydration, maintenance, and nutritional therapy. *MMWR Recomm Rep* 2003;52(RR-16):1–16.

If oral rehydration is chosen, it is best started during an extended period of monitored therapy in the ED, and it may be implemented in any child who can drink and is not in shock. The efficacy of ORT has been established even in the child with emesis accompanying diarrhea. In these children, ORT should be administered in small frequent doses (5 mL q1–2 min) (13,14). Table 224.4 lists a program for mild to moderate dehydration. Table 224.5 lists contraindications to ORT.

TABLE 224.4
Emergency Department (ED) Management of Acute Diarrhea with Mild to Moderate Dehydration

Estimate daily fluid requirements and degree of dehydration

Maintenance: 100 mL/kg for first 10 kg body weight, 50 mL/kg for each additional kg over 11–20 kg, and 20 mL/kg for each kg over 20 kg

Deficit requirement for 5% dehydration is 50 mL/kg

While patient is being monitored in the ED, give 50–100 mL/kg ORS over 4 hrs. ORS is best tolerated as small, frequent volumes rather than larger boluses. If vomiting occurs, give the solution 1–2 teaspoons every 5–10 min

Replace ongoing losses <10 kg body weight: 60–120 cc ORS for each diarrheal stool or episode of emesis; >10 kg body weight: 120–240 cc ORS for each diarrheal stool or episode of emesis

If stable and retaining fluids, the child may be discharged after deficit fluid is replaced, with phone contact 4–6 h later

After initial hydration continue breastfeeding or resumption of an age-appropriate diet

TABLE 224.5
Restrictions to ORT Administration

Hemodynamic shock
Obtunded mental status
Abdominal ileus
Bowel obstruction

ORT consists of two phases of therapy. The first is the rehydration phase, in which fluid and electrolytes are restored. Ideally the first phase is completed within a 3- to 4-hour period. The second phase is the maintenance phase, which includes the replacement of ongoing electrolyte and fluid losses as well as ensuring dietary intake.

After successful oral rehydration, a prompt return to age-appropriate diet is indicated. It should be stressed to parents that the objective is to “feed through” the diarrhea, and that loose stools will persist for a few days but should decrease in volume and frequency (15). Continued feeding is safe and may reduce the duration and volume of diarrhea (14). Early refeeding has not been shown to increase the risk of unscheduled parenteral fluid administration, emesis episodes, or the development of persistent diarrhea (16). In general, smaller but more frequent feedings should be given so that the total daily intake approaches normal (5).

Restricted and progressive diets are no longer recommended (17). Breast-fed infants may continue to feed on demand through both the rehydration and maintenance phases of management. Infants who are bottle-fed should stop feeds during rehydration but should restart them with full-strength formula once the rehydration phase is complete. Restarting full-strength formula allows for a return to full caloric intake. Lactose-free formulas are generally not necessary but may be useful in children who are malnourished, have a severe enteropathy, or have persistent lactose intolerance (17). For older children on a mixed diet, the traditional bland diet of bananas, rice or rice cereal, applesauce, and toast (commonly called the BRAT diet) is no longer recommended. To date, there are no studies to support the use of a bland diet and moreover, the BRAT diet is unnecessarily restrictive and provides suboptimal nutrition (17). Therefore, once hydration has been reestablished, the child’s usual preferred and age-appropriate diet should be resumed, although the

BRAT diet may be incorporated into the child's regular diet if desired. Carbonated soft drinks, juice, gelatin desserts, and foods with significant amounts of simple sugars should be avoided, as the osmotic load may increase the diarrhea.

Most episodes of diarrhea do not require antimicrobial therapy, as the predominant cause of acute diarrhea is viral. Moreover, even when a bacterial etiology is responsible, the majority of acute diarrheal cases are self-limited, and the duration of illness is not shortened by antibiotic therapy. However, antimicrobial therapy should be considered in immunosuppressed children, premature infants, septic infants, those with a toxic appearance, or children with underlying disorders (17).

Bloody diarrhea with PMNs probably represents a bacterial cause, and antibiotic therapy may be considered if *Escherichia coli* O157:H7 and *Salmonella* have been excluded. The association of antibiotic therapy in children with *E. coli* 0157:H7 and the development of hemolytic uremic syndrome (HUS) is controversial. It is currently unknown whether empiric antibiotic therapy increases the risk of HUS (18). A few investigations have reported an increased risk of HUS with empiric antibiotic therapy (19,20). In contrast, others have reported a protective effect or a lack of association (21–23). Therefore, the physician contemplating empiric antibiotic therapy for bloody diarrhea should give careful consideration to the possibility of *E. coli* 0157:H7 infection and the potential for an increased risk of HUS with antibiotics.

Generally, antibiotics should be avoided in *Salmonella* gastroenteritis, but exceptions include certain populations prone to *Salmonella* bacteremia, such as in infants younger than 3 months old and in patients with immunodeficiency, a history of chronic gastrointestinal tract disease, or hemoglobinopathies (5). These high-risk patients should be admitted and given intravenous antibiotics.

In cases where *E. Coli* 0157:H7 and *Salmonella* have been excluded and antimicrobial therapy is required, initial antibiotic selection should be adjusted based on stool culture and sensitivity results (Table 224.6).

TABLE 224.6
Antibiotic Therapy Based on Etiology

Organism	Indications	Therapy
Shigella	Majority are self-limited and do not require antimicrobial agents.	77% of *Shigella* are resistant to ampicillin and 37% resistant to trimethoprim–sulfamethoxazole (TMP/SMX)
	Antibiotics are recommended for: Severe disease	Management depends on susceptibility
	Dysentery	*Shigella* susceptible strains:
	Immunocompromised	TMP/SMX: 8 mg/kg/d divided bid based on the TMP component
		Resistant stain or unknown susceptibility:
		Ceftriaxone: 50–75 mg/kg/d IV divided bid for 5 d
		Azithromycin: 12 mg/kg/d PO for 5 d
Salmonella	Overall antibiotics should be avoided	Ampicillin 200 mg/kg/d IV divided bid for 7–10 d and gentamicin 6–7.5 mg/kg/d IV divided tid
	Antibiotics and hospital admission are recommended for:	
	Infants >3 mos old	
	Immunocompromised	
	Hemoglobinopathies	
C. jejuni		Resistant to TMP/SMX, and should be treated with Erythromycin: 30–50 mg/kg/d divided tid PO for 5–7 d
		Azithromycin for 12 mg/kg/d PO for 5–7 d
Giardia	Presence of *Giardia* on stool testing	Metronidazole: 15 mg/kg/d divided tid for 5–7 d
		Metronidazole has a cure rate of 80–95%.
		Tinidazole: 50 mg/kg once with maximum dose of 2 g
C. difficile	*C. difficile* cytotoxin found in stool	Discontinue any current antibiotics
		In the presence of severe diarrhea or diarrhea that persists despite discontinuation of antibiotics:
		Metronidazole: 30 mg/kg/d divided qid
		Vancomycin: 40 mg/kg/d divided qid for 10 d maximum dose of 500 mg is indicated for cases that do not respond to metronidazole. Vancomycin administration is discouraged secondary to promotion of vancomycin resistant organisms

From American Academy of Pediatrics, Pickering LK, ed. *2006 Red Book: Report of the Committee on Infectious Diseases*, 27th ed. Elk Grove Village, IL: Author; 2006.

The American Academy of Pediatrics does not recommend the use of antiemetic, antisecretory, or antiperistaltic drugs (6). There is a growing body of evidence that *selective* use of antiemetics (particularly ondansetron) may be effective in decreasing the rate of vomiting, improving the success rate of oral hydration, preventing the need for IV hydration, and preventing the need for hospital admission in those receiving IV hydration (see Chapter 223).

The use of narcotic-based agents is specifically contraindicated in bacterial gastroenteritis because they may induce bowel stasis and promote more aggressive bacterial invasion. Some of the adverse events associated with use of such antidiarrhea agents in the pediatric population are ileus, lethargy, and death. A systematic review and meta-analysis found the risks to outweigh the benefits of loperamide, specifically in children less than 3 years of age, in those that are malnourished, moderately or severely dehydrated, or systemically ill, and in the presence of dysentery (24).

Parents should be instructed on hygienic precautions for diaper handling and good hand-washing practices. Strict hand-washing techniques have been demonstrated to reduce the incidence of acute infectious diarrhea in daycare facilities (25). The child should be excluded from the daycare center if there is diarrhea not contained by diaper or toilet use, if stools contain mucus or blood, or if there is associated fever.

CRITICAL INTERVENTIONS

- Recognition and correction of dehydration, acidosis, electrolyte disturbances, hypoglycemia, shock, or associated sepsis
- ORT should be administered over a period of 3 to 4 hours.
- Additional ORS should be administered for ongoing losses.
- Prompt return to an age-appropriate diet once rehydration is achieved
- Selective utilization of antibiotics based on exclusion of *E. Coli* 0157:H7 and *Salmonella* by culture as well as by the criteria listed in Table 224.6
- Avoidance of antisecretory or antiperistaltic medications
- Instruction of parents on hygienic precautions.

DISPOSITION

If more than 5% dehydration is present, a pediatrician should be consulted for probable admission, with rehydration efforts beginning in the ED. With chronic diarrhea, consultation with a pediatrician or pediatric gastroenterologist is in order. Diarrhea may paradoxically complicate surgical conditions (e.g., Hirschsprung disease), in which case a pediatric surgeon should be consulted.

Indications for hospitalization are listed in Table 224.7. Sepsis and serious illness in infants younger than 1 month old may be clinically subtle or occult. Even mild dehydration in young infants deserves careful consideration for admission.

TABLE 224.7
Indications for Admission

Dehydration >5%
Significant electrolyte disturbances
Suspected sepsis
Intractable vomiting
Bilious vomiting
Complicated chronic diarrhea with failure to thrive
Poor social situation
Parental noncompliance or inability to follow prescribed therapy
Suspected deprivation or neglect
Neonate with dehydration

Simple diarrhea with dehydration requires only judicious oral or intravenous rehydration and rarely requires transfer unless there are no inpatient pediatric services. Complicated cases of dehydration (e.g., those associated with hypernatremia) or those of chronic duration usually require specific pediatric expertise.

Common Pitfalls

- Failure to appreciate that the young infant with diarrhea may initially appear well but develop serious dehydration over a short period
- Use of restrictive or progressive diets
- Failure to rely on the caregiver's history of decreased or absent urine output, lethargy, or inability to tolerate fluids may lead to inappropriate management and disposition.
- Underestimation of the degree of hypovolemia and failing to identify subtle signs of shock
- Failure to follow strict hand hygiene

CHAPTER 225 Dehydration

Todd Wylie and Mark S. McIntosh

The diagnosis and management of dehydration in children and infants requires an understanding of fluid and electrolyte balance. Total body water varies with age, ranging from approximately 75% in the term newborn to 65% in the 1-year-old, and decreasing to 55% to 60% in adolescents and adults. Although infants have a greater percentage of total body water than adults, this does not provide extra protection from dehydration. Children, and infants in particular, have larger surface area to body weight ratios, greater resting metabolic rates, and a higher rate of fluid turnover. In fact, fluid turnover in infants is roughly double that of adults. The increased rate of fluid turnover makes infants susceptible to dehydration stemming from excessive losses or lack of fluid intake.

Multiple organ systems and a variety of mechanisms are involved in maintaining electrolyte and fluid balance. Volume status is linked primarily to the concentration of sodium in the extracellular space. Antidiuretic hormone, aldosterone, the renin–angiotensin system, and kidneys work in concert to maintain sodium equilibrium and hence volume status.

CLINICAL PRESENTATION

The clinical presentation of dehydration consists of a spectrum ranging from mild with few or no obvious signs or symptoms, to severe in which signs and symptoms include tachycardia, anuria, lethargy, skin tenting, parched mucous membranes, and hypotension (Table 225.1). The degree of dehydration can be expressed as a proportional deficit of the pre-illness body weight, with deficits of

3% to 5%, 6% to 9%, and ≥10% corresponding to "mild," "moderate," and "severe" dehydration respectively (1).

The clinical presentation is not only influenced by the degree of dehydration as a proportion of weight, but also by the serum sodium concentration. Isonatremic dehydration (Table 225.2), the most common form, is characterized by a proportional loss of both water and electrolytes, as occurs, for example, in children with short bouts of diarrhea. In hyponatremic dehydration, the intravascular volume is compromised as fluid translocates into the intracellular compartment in an effort to maintain osmotic equilibrium. Hyponatremic dehydration may occur as a result of gastroenteritis, renal losses (e.g., proximal renal tubular acidosis, diuretic use, salt-wasting nephropathy), syndrome of inappropriate secretion of antidiuretic hormone (SIADH), or in patients with cystic fibrosis exposed to high environmental temperatures. Infants with hyponatremic dehydration may be prone to exhibiting signs of shock with only moderate dehydration. Hypernatremic dehydration results from a greater loss of water relative to sodium. Causes of hypernatremia include diarrhea in conjunction with a persistent fever, diabetes insipidus, excessive exogenous sodium (e.g., sodium bicarbonate, hypertonic saline, improperly diluted infant formula), and inability to regulate fluid intake. Redistribution of fluid out of the intracellular compartment into the extracellular compartment, as occurs with hypernatremic dehydration, may mask some signs of dehydration, even in the face of significant fluid deficits.

TABLE 225.2
Type of Dehydration Based on Serum Sodium Concentration

Dehydration Type	Serum Sodium Concentration (mEq/L)
Hyponatremic	<130
Isonatremic	130–150
Hypernatremic	>150

DIFFERENTIAL DIAGNOSIS

Dehydration in children usually results from either increased fluid output (gastrointestinal losses, renal loses, insensible losses), decreased fluid intake, or a combination of both. Translocation of fluids, as occurs with significant burns or ascites, may also cause dehydration, though these conditions are less commonly encountered. Increased gastrointestinal losses in the form of diarrhea and vomiting are the most common source of dehydration in children. Estimates of mortality due to diarrheal disease for young children in the developing world range from approximately 1.6 to 2.2 million deaths annually (2). In developed nations, dehydration accounts for significant morbidity in the pediatric population, although the mortality rate is relatively low given the prevalence of disease. In the United States, acute gastroenteritis in children accounts for more than 1.5 million outpatient visits annually, 200,000 hospitalizations, and approximately 300 deaths (3). Increased fluid losses may also occur from renal losses, insensible losses due to fever, increased respiratory rate, and environmental conditions. Renal losses may result from hyperglycemia, diabetic ketoacidosis, congenital adrenal hyperplasia, proximal renal tubular acidosis, diuretic use, and diabetes insipidus. Fever in an infant can increase insensible water losses by approximately 0.42 mL/kg/°C for each degree >37°C. Decreased fluid intake may be secondary to pharyngitis, stomatitis, vomiting, or respiratory distress (particularly in infants). For this reason, any infant presenting with decreased oral intake, fever, vomiting, diarrhea, and especially respiratory distress, regardless of etiology, must be carefully assessed for potential dehydration.

ED EVALUATION

Multiple disease states contribute to dehydration in children. Identification of the source is simplified by focusing on factors that affect intake, loss, or translocation of fluids (e.g., burns, ascites). The frequency and amount of urine, output must be elicited from the history as well as an accurate sense of the volume and composition of oral intake. Losses, in terms of emesis and or diarrhea, must also be characterized and carefully quantified whenever possible. Baseline

body weight, if known, should be compared with the current weight in conjunction with physical examination findings to estimate the degree of dehydration. Dehydration is a clinical diagnosis and the degree of dehydration is best determined by measurement of acute weight loss which directly reflects total body water deficit. However, since an accurate pre-illness weight often is not known in the acute setting, clinical assessment is used to inform estimates of overall fluid deficits. Signs and symptoms used for clinically assessing the degree of dehydration are listed in Table 225.1. The degree of dehydration is generally expressed as a proportion of the pre-illness body weight. As mentioned above, body fluid deficits of 3% to 5%, 6% to 9%, and $\leq$10% correspond to "mild," "moderate," and "severe" dehydration respectively for infants and small children (1). The reliability of clinical parameters for evaluation of dehydration has been evaluated in multiple studies (4–7). One study found the median number of clinical findings varied with degree of dehydration; specifically patients with mild, moderate, or severe dehydration displayed 1, 5, and 8, associated findings, respectively (4). Four specific findings were found to be independently associated with dehydration, including general appearance, capillary refill $>$2 seconds, dry mucous membranes, and reduced tears (4). A meta-analysis reviewing the utility of symptoms and signs for evaluating dehydration in children found abnormal capillary refill time, abnormal skin turgor, and abnormal respiratory pattern to be the most useful signs for predicting 5% dehydration (5). The same study found that a combination of clinical signs predicted dehydration better than any single sign (5). As a general rule, the majority of pediatric emergency department (ED) patients will fall into the mild dehydration category. Patients with fluid losses significant enough to be categorized as moderate dehydration will subjectively appear far more ill than patients with only 3% to 5% weight loss, independent of formal quantification of signs or symptoms.

TABLE 225.1
Clinical Assessment of Hydration Status and Percentage Dehydration

Extent of Dehydration	Mild (3–5%)	Moderate (6–9%)	Severe (≥10%)
Eyes	Normal	Sunken	Markedly sunken
Skin turgor	Normal	Decreased	Tenting
Heart rate	Normal	Slightly increased	Significantly increased
Blood pressure	Normal	Normal to orthostatic	Shock
Mental status	Normal for age	Normal to listless	Depressed/lethargic
Thirst	Slight increase	Moderate increase	Marked increase
Mucous membranes	Normal	Dry	Parched
Tears	Normal	Decreased	Absent
Anterior fontanelle	Normal	Sunken	Markedly sunken
Skin/capillary refill	Normal	Delayed capillary refill	Cool/mottled/poor
Urine output	Unchanged	Decreased	Anuric

Managing acute gastroenteritis among children: Oral rehydration, maintenance, and nutritional therapy. *MMWR Recomm Rep.* 2003;52(RR-16):1–16; Gorelick MH, Shaw KN, Murphy KO. Validity and reliability of clinical signs in the diagnosis of dehydration in children. *Pediatrics*. 1997;99:E6; Steiner MJ, DeWalt DA, Byerley JS. Is this child dehydrated? *JAMA*. 2004;291:2746–2754.

The diagnosis of dehydration does not require the use of laboratory studies, and no single laboratory test reliably identifies the degree of dehydration. However, abnormalities in the serum electrolytes, glucose, blood urea nitrogen (BUN), and other laboratory studies may occur, particularly in children with moderate to severe dehydration (8–11). Serum glucose may be reduced in up to 10% of dehydrated children (8). In one study of children with mild, moderate, or severe dehydration, 48% were found to have one or more serum electrolyte abnormalities, which led to a change in management for 10% of patients (8). In that study, an inappropriately low serum bicarbonate (<16 mmol/L) was the most common abnormality (8). A low serum bicarbonate level has been found to occur in association with dehydration, although it does not always appear to reliably reflect the degree of dehydration (9–11). One study demonstrated that a serum bicarbonate concentration <17 mEq/L was 77% sensitive for predicting moderate dehydration and 94% sensitive for predicting severe dehydration (10). A very low serum bicarbonate (≤ 13 mEq/L) has been associated with a higher clinical degree of dehydration in several studies (8–10). Other laboratory abnormalities either occur less frequently or are unreliable as predictors of dehydration. An elevated BUN level was found to have an association with moderate to severe dehydration if

it was >100 mg/dL, but was not helpful if between 40 mg/dL and 100 mg/dL (11). Another study found that the BUN level did not accurately reflect dehydration (12). The concentrating ability of the kidneys is immature in neonates and young infants; renal blood flow and glomerular filtration do not reach adult values until approximately 1 year of age. This may result in a poor correlation between urine-specific gravity and urine ketones with the degree of dehydration in young children and infants presenting to the ED (13).

Despite the limited utility of laboratory studies in pediatric patients with dehydration, serum electrolytes, BUN, creatinine, and serum glucose should be measured in all patients with moderate to severe dehydration requiring prolonged observation or admission. This is especially true in very young infants and neonates, where metabolic perturbations may present more subtly and be markers of underlying illness. It is vital, however, to appreciate that laboratory studies serve as markers of dehydration severity and not as tools to establish the diagnosis of dehydration. Thoughtful testing in the dehydrated patient in the age of oral rehydration is important as one considers resource utilization from both the point of view of cost containment and ED flow. Venipunctures divert nursing resources away from other patient needs in the ED, since more than one nurse is frequently required to obtain the sample. Realizing that the majority of pediatric ED patients are only mildly dehydrated, a fingerstick glucose measurement may be the best initial test to stratify patients and guide early therapy.

ED MANAGEMENT

Intravenous rehydration is not necessary in all cases of dehydration. There is a strong support for the use of oral rehydration therapy (ORT) in children with mild dehydration secondary to acute gastroenteritis (2,3,14–16). *In most children, ORT is the recommended initial approach to therapy* (2,3). At least two meta-analyses have concluded that ORT is as effective as IV therapy for mild to moderate dehydration associated with gastroenteritis (17,18). Moreover, the time required to initiate therapy with oral rehydration may be less

than that with IV fluid therapy (16), which often exceeds the recommended 4-hour time period (19).

The physiologic basis of ORT is the sodium-glucose cotransport mechanism linking the reabsorption of salt and glucose at the intestinal brush border. Clinical studies, initially in cholera patients and subsequently in patients with viral or bacterial diarrhea, have shown that sodium- and glucose-containing oral solutions are effective in treating dehydration secondary to diarrheal disease.

There are a variety of commercially available oral rehydration solutions (ORSs) (Table 225.3). Most of these solutions have lower concentrations of sodium (45–50 mmol/L) than the solutions originally studied. Although these products were previously thought to be appropriate only for use as maintenance solutions, it is now felt that they can be satisfactorily used to rehydrate children with mild or moderate dehydration (3). In 2002, the World Health Organization recommended the use of a lower osmolality ORS with 75 mmol/L sodium, 75 mmol/L glucose, and total osmolality of 245 mOsm/L (2). Use of this solution has demonstrated fewer unscheduled intravenous infusions, less vomiting, and decreased stool output when compared to the standard formula (20). Parents, as well as health care providers, must be informed that commonly consumed beverages such as colas, sport drinks, and juices are nonphysiologic and should not be used to treat dehydration.

TABLE 225.3
Contents of Oral Rehydration Solutions

Solution	Carbohydrate (g/L)	Na (mmol/L)	K (mmol/L)	Cl (mmol/L)	Base (mmol/L)	Osmolarity (mOsm/L)
WHO ORS (1975)	20	90	20	80	30	311
WHO ORS (2002)	13.5	75	20	65	30	245
Pedialyte	25	45	20	35	30	250
Rehydralyte	25	75	20	65	30	305

Adapted from King CK, Glass R, Bresee JS, et al. Managing acute gastroenteritis among children: Oral rehydration, maintenance, and nutritional therapy. *MMWR Recomm Rep.* 2003;52(RR-16):1–16.

Oral rehydration is accomplished by providing frequent small volumes of an appropriate solution over 2 to 4 hours (Table 225.4). For children with gastroenteritis and minimal or no dehydration, fluid intake in the form of an appropriate ORS compensates for increased losses; one recommended regimen is 10 mL of fluid per

kilogram of body weight for each diarrheal stool and 2 mL of fluid per kilogram of body weight for each emesis (2). With mild to moderate dehydration, the goal is to provide 50 mL/kg over 2 to 4 hours in mildly dehydrated children and 100 mL/kg over 2 to 4 hours in moderately dehydrated children (2,3,14). Therapy is initiated with 5 mL (1 tsp) every 1 to 2 minutes (2,3). The amount can be increased gradually as tolerated. Frozen rehydration solutions can be tried in patients who initially refuse oral fluids or have difficulty tolerating oral fluids. Ongoing losses from diarrhea or emesis should be continually replaced as described.

TABLE 225.4
Guide to Oral Rehydration Therapy

Degree of Dehydration	Rehydration Phase	Replacement of Ongoing Losses	Diet
Mild dehydration	1. Replace fluid deficit over 2–4 hrs using appropriate oral rehydration solution (ORS) 2. Administer ORS in frequent, small amounts: 5 mL every 1–2 min using syringe, spoon, or cup 3. Goal: 50 mL/kg of ORS over 2–4 hrs	Replace ongoing losses from diarrhea (10 mL/kg/watery stool) and vomiting (2 mL/kg/episode of emesis) with ORS.	Return to age-appropriate diet as soon as rehydration phase is complete.
Moderate dehydration	1. Replace fluid deficit over 2–4 hrs using appropriate ORS 2. Administer ORS in frequent, small amounts: 5 mL every 1–2 min using syringe, spoon, or cup 3. Goal: 100 mL/kg of ORS over 2–4 hrs	Replace ongoing losses from diarrhea (10 mL/kg/watery stool) and vomiting (2 mL/kg/episode of emesis) with ORS	Return to age-appropriate diet as soon as rehydration phase complete.

Adapted from King CK, Glass R, Bresee JS, et al. Managing acute gastroenteritis among children: Oral rehydration, maintenance, and nutritional therapy. *MMWR Recomm Rep.* 2003;52(RR-16):1–16.

Patients should have an age-appropriate diet restarted as soon as they have been rehydrated (2,3). Foods that are high in simple sugars (e.g., soft drinks, juices, gelatin desserts) should be avoided because they may worsen diarrhea (2,3). Caretakers should be instructed to have the patient return if losses continue. Refusal of oral fluids or failure to tolerate oral fluids should prompt initiation of intravenous rehydration. Severely dehydrated children and those who do not improve with oral rehydration require intravenous rehydration as well.

Patients who refuse to drink, continue to vomit, or consume inadequate amounts of fluid can present a clinical problem. In this situation, administration of an ORS by nasogastric tube may be an alternative to intravenous rehydration. One prospective study demonstrated that this was as safe and effective as using the IV route (21). Patients who received nasogastric hydration (50 mL/kg over 3

hours) had faster resolution of acidosis, decreased ketonuria, and lower urine-specific gravity than those who received the same amount of IV hydration.

Certain antiemetics remain controversial, primarily because of the adverse effects associated with these medications. However, several studies have shown ondansetron to be relatively safe and effective in the management of acute gastroenteritis in the ED setting (22–24). Oral ondansetron reduces the vomiting associated with acute gastroenteritis, in addition to facilitating oral rehydration and reducing the rate of hospital admission (22,23). Clinicians must keep in mind that ondansetron treats nausea and vomiting, but not the underlying cause(s). Clinicians must assure the effects of ondansetron are not masking important acute causes of vomiting, such as subtle signs of increased intracranial pressure or diabetic ketoacidosis.

Subcutaneous fluid administration is another potential alternative to intravenous rehydration in children with mild to moderate dehydration. Potential benefits of this approach include reported ease of use, safety, efficacy, and parental acceptance (25). Obstacles to the use of subcutaneous fluid administration include a lack of familiarity with the process, and the potential need for hyaluronidase to facilitate success of the procedure. In addition, subcutaneous fluid administration is not indicated for the management of severe dehydration. As the data supporting this technique in children is limited, future studies are necessary to evaluate and determine appropriate settings for implementation.

In moderate and especially in severe dehydration, the immediate goal is to treat shock by rapidly expanding the intravascular volume with intravenous fluids. In the presence of decompensated shock, if intravenous access is not rapidly obtainable, intraosseous access is an alternative (see Chapter 219). Once access is obtained, successive fluid boluses of 20 mL/kg of an isotonic solution are given until clinical improvement is noted. An isotonic crystalloid solution is the only solution recommended for volume resuscitation in these circumstances. Blood should be drawn for laboratory studies, which should include electrolyte levels, BUN, creatinine, and a bedside serum glucose screening to rule out hypoglycemia. Before initiating

fluid therapy, it is important to palpate the liver for size. Cardiogenic shock, although rare, may be misdiagnosed as hypovolemia in the infant or neonate with undiagnosed congenital heart disease, and a few hundred mL of excess fluid, in this instance, could contribute to heart failure.

It is reasonable to administer up to 60 cc/kg of isotonic solution in the initial fluid resuscitation phase. Subsequent boluses may be given as needed with reevaluation after each bolus. Close attention to cardiopulmonary status must be maintained to avoid iatrogenic pulmonary edema. This is particularly true for children with underlying pulmonary or cardiac conditions. If the child is not in shock, the 20-mL/kg fluid bolus may be given more slowly (i.e., over a period of 30 minutes to 1 hour).

Patients with hyponatremic dehydration may present with nausea, vomiting, or seizures. The classic case is the infant who has received improperly prepared overdiluted powdered formula resulting in administration of excess free water. These symptoms typically resolve when the serum sodium is restored to above 125 mEq/L. In the presence of seizures, however, the serum sodium must be rapidly corrected for seizures to resolve. Subtracting the current serum sodium level from the desired level and multiplying by 0.6 and the patient's weight in kilograms provides the amount of 3% saline required for acute correction. An alternative approach is to administer 3 to 5 cc/kg of 3% saline intravenously until seizures terminate.

Subsequent management after rapid repletion of the intravascular space consists of calculating the deficit of fluids and evaluating the acid–base and electrolyte disturbances, but this kind of management is not necessarily the responsibility of the emergency physician. In the consolidation phase, calculating deficit fluids, maintenance fluids, and ongoing losses determines the total volume of fluid required to complete treatment. Sample calculations are illustrated below.

Calculation of Fluid Deficits

1. If the normal baseline weight of the patient is known, the fluid deficit (in liters) is easily calculated with the formula:

Fluid (free water) deficit (liters) = normal wt (kg) − present wt (kg)

2. If the normal weight is not known, it may be calculated by using the patient's estimated percent dehydration and the present weight, using the following formula: Normal wt = present wt × (100/[100 – % dehydration]).
3. Determine whether the dehydration is hypotonic, isotonic, or hypertonic, based on the criteria in Table 225.2 and calculate the sodium and potassium deficits.
4. Calculate the rate of deficit replacement. For isotonic dehydration, half of the deficit is replaced in the first 8 hours, and the second half is replaced over the next 16 hours. This should be given in addition to (and in conjunction with) the maintenance fluids required for the 24-hour period.

Calculation of Maintenance Fluids

1. Free water needs for a 24-hour period are 100 mL/kg/24 hr for the first 10 kg of body weight; 50 mL/kg/24 hr for the second 10 kg; and 20 mL/kg/24 hr for every kg of body weight >20 kg. Alternatively, to calculate per hour needs use 4 mL/kg/hr for the first 10 kg; 2 mL/kg/hr for the next 10 kg; and 1 mL/kg/hr for every kg >20 kg. For example, maintenance fluids for a 25-kg child will be (1,000 mL + 500 mL + 100 mL)/24 hr = 67 mL/hr.
2. Sodium requirements are 2 to 3 mEq/kg/d.
3. Potassium requirements are 1 to 2 mEq/kg/d.

An alternative method for managing fluid needs during the consolidation phase is to replace the remaining calculated fluid deficit over the first 8 hours with $D_5$0.45NS + 20 mEq/L of K^+. Then, the calculated maintenance fluid needs for a 24-hour period are given over the next 16 hours. As 24 hours' worth of maintenance fluid is given over 16 hours, the rate of fluid administration is 1.5 times the usual hourly maintenance rate. To accommodate for

ongoing losses, fluid losses from vomiting and diarrhea can be replaced mL for mL with normal saline every 4 to 6 hours, unless the losses are severe, in which case more frequent replacement may be required. This approach should apply to the majority of dehydrated patients requiring intravenous rehydration.

It is important to note that hypertonic dehydration is not approached in the same manner as above. Overly rapid fluid administration in the setting of hypertonic dehydration may result in fluid shifts with catastrophic repercussions, including cerebral edema and intracranial bleeding. If in shock, the patient should be treated accordingly; but once hemodynamically stabilized, fluids should be given over an extended period of time. The rate of decline in serum sodium should not exceed 10 mEq/L/24 hr.

CRITICAL INTERVENTIONS

- Maintain a low threshold to obtain a bedside glucose measurement in patients with altered mental status or signs of dehydration.
- Use isotonic solutions for bolus intravenous therapy. Never use hypotonic fluids for bolus therapy.
- Reevaluate the patient after every intravenous bolus of fluids before giving another.
- Treat severely dehydrated patients aggressively with adequate volumes of intravenous isotonic fluids.
- In the setting of hypernatremia, reduce the serum sodium concentration slowly.

DISPOSITION

In many centers, the clinical diagnosis of dehydration mandates intravenous therapy and, therefore, admission. This is the more classic and accepted management, but some centers advocate intravenous rehydration over a period of 3 to 4 hours for selected patients in the ED. The physician then determines the need for admission. Infants with severe dehydration by clinical criteria,

acidosis, ongoing losses, electrolyte abnormalities, intolerance to oral fluids, or social needs should be admitted.

Common Pitfalls

- Failure to appreciate the acuity of the ongoing process.
- Failure to recognize and treat shock secondary to dehydration. This includes failing to give boluses of 20 mL/kg until end-organ perfusion is improved, or the use of nonisotonic fluids to accomplish this task.
- Failure to monitor ongoing therapy, which may result in overhydration or underhydration.
- Failure to address associated abnormalities of electrolyte and acid–base balance.
- Failure to address the underlying cause of dehydration (e.g., pyloric stenosis, diabetic ketoacidosis, child abuse or neglect).

CHAPTER 226 Failure to Thrive

Jeffrey Hom

Failure to thrive (FTT) is a common term in pediatrics but lacks a clear definition (1–4). Historically, it refers to a "failure to gain weight" (weight less than the third percentile for age or weight for height below the fifth percentile). In addition, etiologies for FTT were organized into organic versus nonorganic causes. Regardless of cause, the final common pathway is failure to consume adequate nutrition for optimal growth and development. The causes are often complex and multifactorial. FTT has been reported as the seventh most common reason for hospitalization in children's hospitals. Terms such as undernutrition, malnutrition, or weight faltering have evolved as more contemporary descriptors (1,4,5).

CLINICAL PRESENTATION

Infants with FTT may present in extremis secondary to acid–base imbalances, severe anemia, malnourishment, or dehydration. More commonly, however, growth failure may simply be an incidental finding of an observant clinician.

Measuring growth parameters of weight, length, and head circumference determine whether growth failure or undernourishment exists. These parameters should be plotted on growth charts downloadable from the Centers for Disease Control and the National Center for Health Statistics Web site (http://www.cdc.gov/growthcharts/) (6). When possible, comparing them to prior measurements, either from the medical record or at a minimum reported weight from the caregiver, will allow a rough

determination of growth trends. Growth patterns will differentiate between undernourishment (poor weight gain) and poor growth (low weight, short stature, and small head circumference).

DIFFERENTIAL DIAGNOSIS

The etiology of FTT is malnutrition, expect in cases of familial short stature and constitutional growth delay. FTT can be classified into three groups: (1) normal head circumference with weight reduced out of proportion to height (e.g., caloric insufficiency), (2) normal (or enlarged) head circumference with weight moderately reduced in proportion to height (e.g., endocrinopathies), and (3) weight, length, and head circumference all reduced (e.g., fetal alcohol syndrome) (Table 226.1). The most common form is the first, frequently attributed to *caloric insufficiency*. This can be due to inadequate caloric intake, caloric wasting, increase caloric needs, or abnormal regulation. Decreased caloric intake is commonly caused by psychosocial impairment in the child's environment such as poverty, behavioral feeding difficulties, maternal depression, infant–parent bonding, interpersonal violence in the home, Münchausen syndrome by proxy, neglect, or nonaccidental trauma (7–16). The child presents with a markedly decreased weight compared with length and head circumference. Social history and environmental circumstances are vital to this assessment. Caloric intake can also be impaired by organic disease causing regurgitation (e.g., severe gastroesophageal reflux, pyloric stenosis, rumination syndrome), mechanical problems (e.g., sucking/swallowing abnormalities, neurologic disease, perinatal asphyxia), or malabsorption (e.g., cystic fibrosis, lactase deficiency, renal tubular acidosis). An underlying history of chronic disease may also explain the malnutrition.

TABLE 226.1
Classification of Failure to Thrive

Group I

Most common type. Normal head circumference; weight reduced out of proportion to height. In most cases of failure to thrive, malnutrition is present as a result of either deficient caloric intake or malabsorption.

Group II

Normal or enlarged head circumference for age; weight only moderately reduced, usually in proportion to height; structural dystrophies, constitutional dwarfism, endocrinopathies

Group III

Subnormal head circumference; weight reduced in proportion to height; primary central nervous system deficit; intrauterine growth retardation

From Kempe CH, Silver HK, O'Brien D, eds. *Current Pediatric Diagnosis and Treatment*, 6th ed. Los Altos, CA: Lange, 1980:624.

The second group presents with normal or enlarged head circumference with *weight and length equally affected.* Most of these patients have underlying metabolic disorders such as hypothyroidism, growth hormone deficiency, galactosemia, or renal tubular acidosis.

The third group consists of children whose *weight, length, and head circumference* are all reduced. This category includes patients with genetic disorders (e.g., Turner syndrome, structural dystrophies) or congenital problems (e.g., fetal alcohol syndrome, small for gestational age) (1,2,5,17–19).

ED EVALUATION

FTT is multifactorial and patients frequently do not fit cleanly into any one particular group, making the differential diagnosis difficult to manage. The emergency physician's primary role is recognition of growth deficiency. This is more difficult to do when caretakers use the emergency department (ED) as their primary care outlet where growth records are not routinely maintained. When a child is brought to the ED with an acute illness, physicians can easily fail to recognize the insidious and more serious problem of growth failure. Weight measurements should be part of the initial evaluation of *all* children seen in the ED, and be routinely charted, ideally on a growth chart. When the diagnosis of FTT is suspected, a thorough

history (with in-depth social history), physical examination, and growth pattern evaluation must be performed.

Laboratory tests are of limited value in most cases, but they can help diagnose serious conditions that require immediate attention. Tests commonly performed in the ED are a complete blood count with differential, urinalysis with culture, serum electrolytes, calcium, phosphorous, albumin, and total protein (2). More specific tests should be individualized, such as thyroid function tests and human immunodeficiency virus. Imaging studies should be directed to specific concerns (suspected congenital heart disease, nonaccidental trauma, malnutrition). If nonaccidental trauma or neglect is suspected, proper referral to child protective services and law enforcement should be made.

KEY TESTING

- Confirm that weight loss is persistent and substantial, that is, supportive weight, length, and head circumference from different times are needed for confirmation.
- Isolated laboratory testing does not confirm the diagnosis, rather it rules in or rules out specific diagnosis, related to the patient's growth retardation.
- CBC, electrolytes, calcium, phosphorous, albumin and total protein, urinalysis and culture
- Thyroid function, HIV testing as indicated
- CXR for congenital heart disease if suspected. Extremity images, skeletal survey, and/or head CT in cases of suspected child abuse
- History and physical examination are central for assessment. Assessment for the three causes of FTT: (1) inadequate intake of nutrient or appropriate nutritional content, (2) improper absorption of nutrition, and (3) increased metabolic demands due to chronic disease or genetic or metabolic disorders.

ED MANAGEMENT

The emergency physician's primary responsibility is to recognize FTT and not necessarily determine its cause. As with any patient in

the ED, assessing for medical stability is first and foremost. Airway, breathing, and circulation may all be affected in severe cases of FTT as a consequence of acid–base status from dehydration or an underlying metabolic abnormality. Most commonly, infants with FTT present to the ED in a stable condition. The growth failure may be associated with chief complaints such as vomiting or poor feeding or may be an incidental finding by an astute physician.

CRITICAL INTERVENTIONS

- Address the ABCs, which may be compromised in children who are medically unstable from severe dehydration, acidosis, trauma (nonaccidental trauma), or underlying metabolic disorder.
- Recognition of malnutrition.
- Recognition of possible nonaccidental trauma and/or neglect.
- Recognition of the indications for hospitalization:
  - Medical instability
  - Nonaccidental trauma/neglect with no options for safe placement
  - Severe undernourishment
  - Laboratory abnormalities indicating medical instability

DISPOSITION

To facilitate evaluation and promote feeding, patients with FTT were traditionally admitted. Hospitalizations promoted prolonged inpatient stays that were disruptive to the child and family; therefore hospitalizations are currently reserved for patients exposed to frank neglect, unstable home or social situations, and/or with definitive medical problems (1,2).

Outpatient management is encouraged if the FTT is: (1) mild or has no obvious organic cause, (2) the medical provider is comfortable with the social environment to which the infant will be discharged, and (3) follow-up with the primary physician is established. Ensuring the child has a medical home is imperative. A multidisciplinary team approach, involving a social worker, psychiatrist, and nutritionist, enhances success in both inpatient and

outpatient management. Healthcare provider home visitation has demonstrated significantly improved growth rates of affected children, compared with conventional management (4,20). In all cases of FTT, communication between the emergency physician and the primary physician is critical to effective decision making.

Common Pitfalls

- Failing to recognize FTT by addressing only the acute illness of presentation.
- Failing to look for signs and symptoms of nonaccidental trauma and/or neglect.
- Failing to consider social, environmental and physiologic factors as they impact growth failure.
- Failing to provide adequate follow-up.

CHAPTER 227

Crying, Fussy Infant

Naghma S. Khan

Mammals and birds use vocal signals to get attention. In humans the cry of the newborn promotes the release of oxytocin in the mother, which is essential not only for infant nutrition, but also for the development of attachment between mothers and their infants (1,2). Excessive crying usually signals an unmet need or distress and evokes significant apprehension and stress in both caregivers and healthcare providers. Persistent crying has been shown to contribute to family stress and plays a significant role in child abuse (3). Normal infant crying lasts less than 3 hours per day and peaks between 3 PM and 11 PM (1,4). Emergency physicians must be able to distinguish prevalent "normal" crying from crying indicative of acute or life-threatening illness that requires immediate intervention.

CLINICAL PRESENTATION

Parental temperament and experience greatly determine the crying threshold where medical help is sought. A visit to the emergency department (ED) is most likely to be precipitated by prolonged, inconsolable, and recurrent episodes of crying or a single act of crying that is abnormally high-pitched or perceived to be associated with pain (4). Most commonly, the presentation is in the late evening or the middle of the night and caregivers are anxious, frustrated, and sleep deprived. A febrile infant with extreme irritability and fussiness does not pose as much of a diagnostic challenge as does an afebrile child with the same symptoms (5).

DIFFERENTIAL DIAGNOSIS

It is important to differentiate recurrent benign crying syndromes (such as colic) from those that may be the harbinger of a limb or life-threatening disease. The differential diagnosis is broad and involves virtually every organ system (6,7).

Traumatic injuries are a frequent cause of crying and range from a strangulated digit, penis, or clitoris (usually by an encircling hair or a sock fiber) to insect bites and anal fissures, to more serious instances of head trauma, rib or extremity fractures. Signs of child abuse and neglect must be carefully sought; potentially life-threatening injuries can be easily missed. A bulging fontanel may suggest increased intracranial pressure, which may be related to either meningitis or intracranial bleeding. Milk bottles heated in the microwave can cause scald burns on the buccal mucosa or tongue. Open diaper pins in cloth diapers and pain at vaccination sites after the diphtheria–pertussis–tetanus vaccination can also lead to unexplained crying (8). Corneal abrasions are fairly easy to rule out with fluorescein staining and should be a strong consideration when other more serious or obvious causes have been ruled out (9).

Nontraumatic or infectious causes are also important to consider. An acute suppurative otitis media is easy to miss since the tympanic membrane in infants is horizontal, rather than vertically oriented, and the external canal is narrow. Septic arthritis and osteomyelitis should be considered, in addition to other forms of invasive bacterial illness; these may present more subtly and can be difficult to diagnose. A high degree of suspicion and a careful physical examination are required to evaluate for intussusception, testicular torsion, and incarcerated hernias; thresholds for imaging if any of these are suspected should be low. Cardiac causes include a tetralogy of Fallot spell, congestive heart failure, or supraventricular tachycardia. Many of these patients will have a well-established history of congenital heart disease, but a few will not. A history of difficulty feeding is often a telltale sign. Cocaine exposure (including passive inhalation) and drug withdrawal are also an important part of the differential diagnosis (6,7,10).

It is vital to note *infantile colic is a diagnosis of exclusion in an ED setting*. It is arbitrarily defined by the rule of threes: an otherwise healthy, thriving infant crying for more than 3 hours a day, more than 3 days in a week, for more than 3 weeks. The cry is paroxysmal, develops into a piercing scream, with legs drawn up, abdominal distention, and passage of flatus. The infant appears to be in severe abdominal pain (11,12). Cow's milk allergy, infant temperament, overstimulation, and gastroesophageal reflux have been implicated in the cause of "colic," but others regard it as the extreme end of the normal crying spectrum (5,11,13). Regardless of cause, there is spontaneous resolution by 3 to 4 months of age.

Table 227.1 lists conditions associated with the abrupt onset of inconsolable crying in young infants.

TABLE 227.1
Causes of Excessive Crying in Afebrile Infants

Head and Neck

Head
- Head trauma (intracranial hemorrhage, shaken baby syndrome)
- Meningitis/encephalitis

Eye
- Corneal abrasions
- Ocular foreign body

Ear
- Otitis media

Throat
- Oral mucosal burns
- Teething
- Herpangina/herpes stomatitis/oral thrush
- Foreign body in oropharynx

Chest

Cardiac
- Supraventricular tachycardia
- Congestive heart failure
- Coarctation of the aorta
- Anomalous left coronary artery

Respiratory
- Pneumonia
- Rib fractures

Abdomen

Intussusception, volvulus
Appendicitis
Gastroenteritis
Constipation
Gastroesophageal reflux

Genitourinary

Urinary tract infection
Incarcerated hernia
Strangulated penis, clitoris (hair tourniquet syndrome)
Torsion testis

Extremities

Fractures
Strangulated digit (hair tourniquet syndrome)
Osteomyelitis/Septic arthritis
Open pin in diaper
Pain at vaccination site (especially after diphtheria–pertussis–tetanus vaccine)
Insect bites (brown recluse spider)

Metabolic

Inborn errors of metabolism
Metabolic acidosis
Aspirin overdose

Miscellaneous

Colic
Night terrors
Overstimulation
Maternal depression
Environmental deprivation (starvation, neglect)

DIAGNOSTIC APPROACH

A thorough history and physical examination remains the cornerstone of making the diagnosis. Review the vital signs. The infant should be undressed fully, including removal of the diaper. Carefully inspect the skin for bruises, inflammation, injury, or rash. Palpate the long bones, ribs and clavicles, and check the joints for mobility. Examine the corneas after fluorescein staining and evert the eyelids to check for a foreign body. Carefully examine for hernias, and check for anal fissures. The presence of fever and excessive crying in an infant less than 8 weeks of age mandates a sepsis workup. In one study, only 5% of afebrile infants were noted to have a serious underlying cause for crying, with urinary tract infections being the most common cause. The diagnosis of serious infection was made by the history and physical examination alone in 66% of the infants and by a single diagnostic test (urinalysis and urine culture) in 1.5% of cases. Thus screening for urinary tract infection is mandatory in afebrile crying infant in the first few months of life. Other investigations should be performed on the basis of clinical findings (6,7).

The head should be examined for any signs of trauma or a bulging fontanel. An abdominal examination is difficult to perform in a crying infant. It is important to examine the abdomen and chest, listening to the heart before attempting any invasive or painful procedures; if possible, this examination should be done while the infant is in the mother's lap and sucking on a bottle or pacifier. Flexing the legs at the hip may help relax the abdominal muscles enough to allow for a good abdominal examination. Before attempting a rectal examination, the physician should check the anal area for signs of trauma or anal fissures.

If a careful history and physical examination do not reveal or suggest a cause for crying, further studies are indicated. At a minimum, a catheterized or suprapubic urine sample must be obtained to rule out a urinary infection. A skeletal survey, cranial computed tomography (CT), and an alanine and aspartate

aminotransferase (ALT/AST) are indicated in suspected child abuse to look for healing fractures, intracranial bleeding, or a liver injury, respectively. If an abnormal cardiac rhythm is auscultated, a 12-lead electrocardiogram and a chest radiograph may lead to a diagnosis. Suspected gastrointestinal (GI) emergencies like intussusception and small bowel obstruction should be confirmed with appropriate studies, such as an abdominal ultrasound or an air contrast enema or upper GI series. A sepsis workup is indicated if there is any suspicion of an infectious etiology, especially in a febrile neonate.

CRITICAL INTERVENTIONS

- An in-depth history and physical examination of a fully undressed infant is essential.
- Colic should be a diagnosis of exclusion.
- If the diagnosis is not obvious, consider obtaining a urinalysis to rule out urinary tract infection.
- Fluorescein staining is simple, noninvasive, and diagnostic for corneal abrasion.
- In febrile infants, perform a full sepsis workup to rule out sepsis or meningitis
- Have a high index of suspicion for abuse. A good funduscopic examination to rule out retinal hemorrhages may require dilation of the pupils.

DISPOSITION

Disposition, including subspecialty consultation and treatment, is based on the clinical findings and diagnosis. Parents who present to the ED with a crying infant may not readily accept the physician's judgment that the crying is not a sign of a serious condition and may insist on medication, or another solution. These parents are typically stressed, sleep-deprived, and genuinely afraid for the welfare of their child; they may require a great deal of time to carefully discuss their child's evaluation and assessment.

Only 4% of infants benefit from formula change to a protein hydrolysate formula, because of an underlying cow's milk allergy

(14). Probiotics may or may not be of benefit, but have not been shown to be harmful (15,16). There is no evidence to support gastroesophageal reflux as a cause of excessive crying, and proton pump inhibitors are not recommended (13). Multiple studies have shown the danger of using alcohol-based preparations and Dramamine–Donnatal combinations for colic (17). If no treatable cause for the infant's crying is identified, it is important to empathize with the parents and take time to counsel them on methods to console the child early; possible interventions include rocking slowly in a quiet room, warm compresses to the abdomen, frequent feeding, and burping. Parents should be counseled never to shake the infant, even gently, because of the risk of shaken baby syndrome.

All children who present to the ED with crying need appropriate follow-up, especially if the diagnosis is "colic." Consultation with subspecialists and admission are determined by the diagnosis.

Common Pitfalls

- Taking a hurried and superficial history and not listening to the parents.
- Failure to completely expose the infant for a comprehensive physical examination.
- Ignoring abnormal vital signs.
- Failure to rule out a urinary tract infection.
- Failure to consider child abuse or neglect.
- Failure to sit and *carefully* listen to parents' concerns.

CHAPTER 228
Abdominal Pain

Loren G. Yamamoto

CLINICAL PRESENTATION

Abdominal pain is a common complaint in children presenting to the emergency department (ED), with an extensive differential diagnosis and variable age-dependent clinical presentations. The emergency physician must be able to identify those patients with serious causes (Table 228.1). There are broad principles that may guide the emergency physician in navigating the wide range of possible diagnoses related to pediatric abdominal pain. Ischemic pain typically has a sudden onset, as is seen with torsion or volvulus. Obstruction is most commonly associated with the entities in the mnemonic "double-AIM" (A-A-I-I-M-M): *a*ppendicitis, *a*dhesions, *i*ncarcerated inguinal hernia, *i*ntussusception, *m*alrotation/midgut volvulus, and *M*eckel diverticulum. If the evaluation suggests peritonitis, the most frequent etiology is appendicitis, but other acute surgical conditions are possible as well. Nonbowel conditions such as pyelonephritis or sickle cell disease should also be considered.

TABLE 228.1
Differential Diagnosis of Abdominal Pain in Children

Infants	Toddlers	School-Aged	Teenager
Colic	Acute gastroenteritis	Idiopathic	Appendicitis
Intussusception	Urinary tract infection	Appendicitis	Pelvic Inflammatory Disease
Malrotation	Constipation	Acute gastroenteritis	Peptic ulcer disease
Volvulus	Referred pain	Constipation	Ectopic pregnancy
Hirschsprung disease	Appendicitis	Urinary tract infection	Mittelschmerz
Necrotizing enterocolitis		Peptic ulcer disease	Ovarian/testicular torsion
Incarcerated hernia			

DIFFERENTIAL DIAGNOSIS

In infancy, *colic* is a common cause of abdominal pain (1). The predominant symptom is excessive crying. The infant may have mild abdominal distention and may pull the knees up as if in pain. This typically occurs in the evening and is associated with facial flushing and passing flatus (1). The physical examination, except for the crying, is often unremarkable. Management options are limited to encouraging breast-feeding or trying bottle feeds of a protein hydrolysate formula. It is prudent for breast-feeding mothers to avoid stimulants and spicy foods. It may be difficult to confidently rule out a more serious condition, and laboratory or imaging studies may be required if a serious diagnosis cannot be excluded (see Chapter 227). A prolonged ED observation period may be useful to rule out a serious cause.

Vomiting is abnormal in a neonate and suggests obstruction or a potentially serious infection. Necrotizing enterocolitis occurs in premature infants, but it is known to occur in term infants as well (2). Bilous vomiting in a neonate and in infants up to 12 months of age should be considered a midgut volvulus until proven otherwise (2). In older infants and children, vomiting due to gastroenteritis is common, but vomiting due to gastroenteritis is usually not accompanied by abdominal pain. When vomiting occurs in conjunction with observational evidence of abdominal pain, a more serious diagnosis should be considered. Abdominal distention (with or without bilious vomiting) is suggestive of a more serious disorder. Nonsurgical causes of bilious vomiting may include sepsis, urinary tract infection, and inborn errors of metabolism. Surgical causes may

include intussusception, malrotation complicated by midgut volvulus, and appendicitis.

Intussusception can be defined as a telescoping of a proximal section of bowel (the lead point is called the *intussusceptum*) into a more distal segment (the *intussuscipiens*). This results in a bowel obstruction with consequent ischemia. This most commonly occurs in children less than 2 years of age, but it can occur in older children and should remain part of the differential diagnosis at least through the age of 4. There is typically a dramatic, acute onset of pain (manifested by crying and/or curling up) that is associated with vomiting which often comes in cycles every 3 to 20 minutes, with the child relatively normal or drowsy between episodes (2). The classic triad of intussusception (colicky abdominal pain, emesis, and bloody stools) is not present in the vast majority of patients (3,4). The term "currant jelly" stool is often used to refer to bloody, mucousy stool, which is typically a late finding and is rarely seen. Intussusception should be considered when there is hematemesis or any blood in the stool (dysentery, maroon stool, etc.). Younger infants may present with profound lethargy, *without vomiting* or *abdominal pain* (2,3). A right-sided sausage-shaped abdominal mass is sometimes palpable when the child is relaxed or drowsy. Intussusception usually starts in the cecum, with the ileum intussuscepting into the ascending colon. Thus, clinical and radiographic investigations should focus on the right side.

Malrotation complicated by midgut volvulus is a surgical emergency (2,4). Normally the mesentery attaches broadly to the entire posterior abdominal wall. In malrotation, the mesentery and the vessels responsible for perfusing the bowel are instead attached to a more focal location forming "guts on a stalk", which can twist, resulting in a catastrophic midgut volvulus (2). These infants often present with an acute onset of pain followed by distention and bilious vomiting. Severe ischemia of the entire small bowel develops rapidly, and necrosis can occur in 1 to 2 hours. Although most patients with malrotation present with acute midgut volvulus during infancy, the malrotation can be silent and present later in childhood with an acute midgut volvulus. Some patients may experience a

volvulus that spontaneously reduces while others may have intermittent symptoms to suggest an “intermittent volvulus”; this is best identified by an upper gastrointestinal (GI) series. The upper GI series is the study of choice; a lower GI study may miss some cases (2,4).

Appendicitis in infants often presents with peritonitis; perforation occurs in approximately 85% of infants (5). The infant may have irritability, crying, refusal of feedings, and vomiting, in conjunction with fever, distention, shallow, grunting respirations, and shock (2,5). An indurated and erythematous abdominal wall may be present in these delayed presentations. Older children present with more classic symptoms of appendicitis, such as low-grade fever, anorexia, and periumbilical pain that localizes to the right lower quadrant. On physical examination, tenderness in the right lower quadrant and peritoneal signs may be noted (5,6). Appendicitis is very common and it commonly presents in an atypical fashion (6,7). In comparisons of clinical scoring methods, the Alvarado score (8) and the Pediatric Appendicitis score (PAS) (9) performed the best but neither were sufficiently diagnostic to be used alone (6,7). Since it is difficult to confirm appendicitis clinically (especially early on), advanced imaging studies are often employed.

Meckel diverticulum, located in the jejunum or ileum, can cause a diverse set of serious acute surgical conditions (2,10). The diverticulum contains acid-secreting gastric mucosa that may cause a bleeding ulcer and present with painless rectal bleeding. Also, being a tubular pouch, it may become inflamed (similarly to the appendix), resulting in Meckel diverticulitis (similar to appendicitis, but with pain in an atypical location). Meckel diverticulum may occasionally ulcerate, and perforate, and present as a bowel perforation without the preceding symptoms of diverticulitis. Meckel diverticulum may be attached to the abdominal wall (near the umbilicus) by a stalk-like connection around which a volvulus can occur (similar to malrotation). A Meckel can also form a lead point for intussusception (often ileo-ileal intussusception). Meckel diverticulum is said to follow the rule of 2s: present in 2% of the population, only 2% of these patients manifest clinical problems, symptoms commonly occur

at 2 years of age, the diverticulum is usually 2 in long, and its typical location is 2 ft proximal to the terminal ileum (2,10).

Hirschsprung disease (congenital aganglionosis of the distal colon) usually presents insidiously with constipation, episodes of recurrent crampy abdominal pain, and/or poor weight gain; alternatively, it may present acutely with peritonitis, acute abdominal pain, or bowel obstruction. The diagnosis is made on rectal biopsy or by barium enema that demonstrates a "transition zone" between the dilated proximal colon (normal ganglionic colon) and the nondilated (abnormal aganglionic) distal colon. Patients who have had a surgical resection of the distal aganglionic colon are at risk for "enterocolitis," a condition of severe gastroenteritis functionally resulting in bowel obstruction and requiring hospitalization for IV fluids and rectal dilation.

Gastroesophageal reflux may present with only a vague suggestion of abdominal or esophageal pain and manifested only as irritability. Other symptoms include failure to thrive, respiratory disturbances (wheezing, recurrent cough, pneumonia), or ALTE (apparent life-threatening event) (11). Peptic ulcer disease is uncommon in infants but should be considered in adolescents.

Recurrent abdominal pain is a common somatic complaint of children and is most often found to have no organic cause. Red flags for organic disease include fever, vomiting, weight loss, poor growth, delayed puberty, night awakening, anemia, bloody stools, localized pain or tenderness, and family history of inflammatory bowel disease or peptic ulcer disease (12,13).

Cholecystitis and *cholelithiasis* are generally considered to be uncommon, yet studies show an increasing incidence, partially due to the increasing use of ultrasound. Risk factors for cholelithiasis include parenteral nutrition, hemolytic disease, Kawasaki disease, cystic fibrosis, and obesity. As the teen years approach, cholelithiasis and cholecystitis become more common, and are often associated with female gender, obesity, and positive family history (14,15).

Abdominal pain may be the chief and only complaint after *trauma.* Signs of hemodynamic instability suggest spleen or liver injury. Peritoneal signs suggest a hollow viscous injury or free peritoneal

blood. Delayed presentation with recurrent emesis may indicate a duodenal hematoma or traumatic pancreatitis (not an uncommon sequelae of handlebar injuries).

In postpubertal females with abdominal pain, a source in the reproductive tract, such as ectopic pregnancy, pelvic inflammatory disease, tuboovarian abscess, ovarian torsion, or corpus luteal cyst, must be carefully considered. Secondary sexual maturity characteristics (Tanner stage) suggesting puberty in a female who has not had her first menstrual period (premenarche) raises the possibility of an imperforate hymen and subsequent hematocolpos.

Abdominal pain and fever in the child with immunodeficiency, nephrotic syndrome, or ascites suggests primary peritonitis. Sexual abuse may manifest as a vague abdominal complaint in some children. A high degree of suspicion is required for the emergency physician to include this possibility in the differential diagnosis.

The most common ED cause of pediatric abdominal pain is abdominal cramping due to the failure of stool to move forward with peristalsis. As stool moves distally through the colon, it may fail to move forward (e.g., at the splenic flexure). The colon then contracts more forcefully, resulting in crampy abdominal pain that suddenly remits once the stool moves forward and normal peristalsis resumes. This is sometimes called *constipation,* but the term is often used loosely to refer to painful defecation, difficulty with defecation, the passage of hard stools, or the failure to have a bowel movement every day (see Chapter 230).

DIAGNOSTIC APPROACH

A detailed history is useful but can be misleading as well. In particular, some children with appendicitis are fairly stoic, ambulatory, and complain of only mild abdominal pain, demonstrating few if any of the classic historical elements of appendicitis. Assessing the quality and severity of pain is difficult and unreliable.

Approach the physical examination in a friendly manner; younger children may remain on the parent's lap. Ask parents to bounce a young child gently while being held; most children are comforted by

this, but crying or signs of discomfort may suggest peritonitis. Inspection for distention, asymmetry, or abdominal wall erythema is followed by auscultation with a warm stethoscope. If the parent is carrying the child, the examiner can palpate the abdomen from behind, by bringing his or her hands around the child's abdomen. Palpation in the supine position should then proceed, palpating very slowly for tenderness or masses, initially in the area of the abdomen away from the suspected pathology. The groin and genitals should always be examined for inguinal hernias, scrotal or testicular abnormalities, or vaginal abnormalities. A rectal examination should be performed only if there is a specific indication (e.g., checking for stool impaction or for occult blood) (16). A pelvic examination may be indicated in sexually active or pubertal females.

Ill-appearing patients require IV fluid resuscitation and other indicated treatments. Surgical and radiologic consultation, if needed, should be promptly obtained. In some instances, a constellation of signs and symptoms may suggest a particular diagnosis. For example, painless rectal bleeding suggests a Meckel diverticulum; vomiting, bloody stools, and colicky abdominal pain suggest intussusception. Obtain an imaging study that can help to establish an early diagnosis of a serious condition.

Plain radiographic criteria for identifying a bowel obstruction in children are different from those in adults. These include bowel gas maldistribution, a paucity or excess of bowel gas, dilated bowel (smooth bowel walls with loss of haustra and plications), and large air–fluid levels with J-turns (also known as *hairpin loops* or *candy cane loops*). Plain-film radiographic signs of intussusception include the target sign, the crescent sign, absence of the subhepatic angle, and bowel obstruction (2). Pneumonia causes abdominal pain and is frequently missed on abdominal films because the lung, visible at the upper margin of the film, is easily overlooked. Many children have abdominal films that reveal a large amount of stool. If pain and other symptoms resolve completely after an enema, the child can be discharged home, but if symptoms persist further evaluation is necessary.

The preferred advanced imaging study of choice is evolving. CT scanning was used frequently in the recent past because of its high definition, rapid scan time, and wide availability. As part of the informed consent process, patients and parents should be counseled about the risk of radiation exposure. Ultrasound is less diagnostic, but involves no radiation exposure and can frequently be completed without sedation. The limited availability of trained pediatric ultrasound technicians is a potential disadvantage, but many emergency physicians have, or are acquiring, bedside ultrasound skills in this area. Magnetic resonance imaging (MRI) has an expanding role due to its increasing availability, expanding indications, focused scanning sequence strategies, lack of ionizing radiation, and more widespread availability of pediatric sedation. Study selection depends on facility expertise, resource availability, clinical application, and the availability of sedation, if needed. However, when a clear surgical diagnosis is established clinically, no imaging studies are required and prompt surgical intervention is warranted.

For appendicitis, the diagnostic accuracy of CT is slightly superior to that of ultrasound (17). Since the radiation exposure from CT is of concern, ultrasound is most often chosen as the initial advanced imaging study in a staged approach (18,19). The presence of pelvic free fluid increases the likelihood of appendicitis, while its absence decreases the likelihood (20). However, ultrasound is frequently nondiagnostic (the appendix cannot be visualized). Many studies report that CT is used more frequently at night due to lack of ultrasound services during late evening and night shifts (6). CT is often performed after a nondiagnostic ultrasound; however, its use may be declining (18,6,19) as experience with ultrasound accumulates. Some studies support the use of MRI after an inconclusive ultrasound examination (21). The use of MRI may increase in the future due to its increasing availability and known safety profile.

Intussusception can be reliably diagnosed by ultrasound, making it the study of choice when this diagnosis is suspected (3,4). Plain film x-rays can sometimes confirm the diagnosis, but ultrasound is clearly

superior (3). Once intussusception is confirmed, a contrast enema (air, barium, or water-soluble contrast under fluoroscopy) should be performed in a timely fashion to reduce the intussusception and obviate the need for surgery. The type of contrast should be at the discretion of the radiologist performing the procedure.

If the clinical presentation and plain film radiographs suggest a midgut volvulus, an upper GI series may demonstrate the corkscrew shape of twisted bowel or a halt in the progress of barium at the ligament of Treitz (2). If the clinical presentation suggests intermittent volvulus, an upper GI series remains the best test to identify the malrotation (2,4).

Barium enema and upper GI series often fail to identify Meckel diverticulum, and a "Meckel scan" (nuclear medicine scintigraphy) can then be performed to make the diagnosis. The radioisotope is taken up by gastric mucosa, so it typically images the stomach, but it can also identify ectopic acid-secreting gastric mucosa (2).

DISPOSITION

For seriously ill patients with a surgical abdomen, a surgeon should be consulted immediately while resuscitation measures are instituted. For patients who are less acutely ill, surgical consultation can be initiated after the diagnosis condition has been made or when the diagnosis is still in doubt after initial testing. Surgical emergencies in infants require a surgeon with specific pediatric expertise.

In most cases, advanced imaging studies permit the diagnosis of disorders requiring hospitalization to be made during the ED encounter. In unclear cases, patients should be admitted for observation until an abdominal emergency can be excluded. Given the variability in presentations, it is vital for emergency physicians to appreciate the value of observation as a diagnostic test in children with abdominal pain.

Patients with intussusception whose history suggests a short duration of symptoms and who are doing well following contrast enema reduction, can be discharged following a period of ED observation (2,4,22). While appendicitis is generally considered to be

a condition requiring surgery, a nonsurgical antibiotic option can be considered (23). Both options should be included in the informed consent process.

Low-risk cases can be discharged to home without an advanced imaging study. Regardless of the diagnostic impression at discharge, patients should be discharged with a standardized set of "abdominal pain" instructions stating that the diagnosis is never certain and that the specific cause of abdominal pain can often be difficult to determine. It should list signs and symptoms of serious causes of abdominal pain (appendicitis, intussusception, bowel obstruction, GI bleeding, etc.) that require an immediate return to the ED.

Common Pitfalls

- Approximately 50% of patients with acute appendicitis present with atypical features.
- Midgut volvulus is a true surgical emergency that should be considered in all infants with bilious vomiting.
- Intussusception is easily missed. Abdominal pain or blood in the stool should raise suspicion of this entity.
- Bloody diarrhea, though often due to bacterial dysentery such as shigellosis, may be due to intussusception. Currant jelly stools occur in the minority of cases. Any type of blood in the stool may be due to intussusception

CHAPTER 229

Gastrointestinal Bleeding

Michael Gayle and Niranjan Kissoon

Gastrointestinal (GI) bleeding in children is uncommon with reported incidence available for critically ill children only (1). While the common causes of GI bleeding vary with the child's age, the site of bleeding and character of the blood is age independent, and provides important clues in diagnosis and therapy. For instance, hematemesis (vomiting of blood) implies a source proximal to the ligament of Treitz. Vomited blood may have the appearance of coffee grounds or may be bright red, implying ongoing bleeding. Blood from the upper GI tract or proximal small bowel, when passed per rectum, is typically black or tarry, is sticky, has a characteristic aroma and is termed *melena.* Bright red blood per rectum or maroon stools (hematochezia) implies a more distal GI source (2). Upper GI bleeding, however, if blood loss is considerable and transit time is short, may present as hematochezia.

GI bleeding is an alarming problem in children, with many causes that are common to both children and adults. However, lesions such as necrotizing enterocolitis (NEC) or allergic colitis are unique to pediatrics (3). **Tables 229.1** and **229.2** outline the causes of GI bleeding in children and illustrate the wide, age-related differential diagnosis (2,4,5).

TABLE 229.1
Differential Diagnosis of Upper GI Bleeding

Newborn (0–1 mo)	Preschool (2–5 yrs)
Idiopathic	Esophagitis
Swallowed maternal blood	Gastritis
Esophagitis	Peptic ulcer
Gastritis	Varices (esophageal, gastric)
Stress ulcer	Mallory–Weiss tear
Vitamin K deficiency	Foreign body
Bleeding disorders	Bleeding disorders
Vascular anomalies	Vascular anomalies
Infant (1 mo–2 yrs)	**School Age (>5 yrs)**
Esophagitis	Esophagitis
Gastritis	Gastritis
Stress ulcer	Peptic ulcer
Mallory–Weiss tear	Varices (esophageal, gastric)
Vascular anomalies	Mallory–Weiss tear
Foreign body	Inflammatory bowel disease
Duplication	

TABLE 229.2
Differential Diagnosis of Lower GI Bleeding

Newborn (0–1 mo)	Preschool (2–5 yrs)
Anal fissure	Anal fissure
Local trauma	Polyps
Swallowed maternal blood	Infectious colitis
Upper GI bleeding	Meckel diverticulum
Necrotizing enterocolitis	Hemolytic–uremic syndrome
Malrotation with volvulus	Henoch–Schönlein purpura
Infectious colitis	Inflammatory bowel disease
Hirschsprung disease	Intussusception
Allergic colitis	Pseudomembranous colitis
Coagulopathy	Lymphonodular hyperplasia
Infant (1 mo–2 yrs)	**School Age (>5 yrs)**
Anal fissure	Anal fissure
Hirschsprung disease	Polyps
Allergic colitis	Infectious colitis
Intussusception	Hemorrhoids
Infectious colitis	Inflammatory bowel disease
Meckel diverticulum	Pseudomembranous colitis
Intestinal duplication	Lymphonodular hyperplasia
Lymphonodular hyperplasia	Hemolytic–uremic syndrome
Pseudomembranous colitis	Meckel diverticulum
Polyps	

CLINICAL PRESENTATION

Bleeding from anal fissures or from the upper GI tract is the most common reason children with GI bleeding visit the emergency department (ED). Life-threatening hemorrhage is rare and more likely to present as hemorrhagic shock. The GI tract as the source of bleeding is usually obvious although GI bleeding in a child may present as microcytic anemia from chronic upper GI bleeding or occult bleeding in the stool (e.g., cow's milk protein hypersensitivity) (2,6). The increased use of NSAIDs such as ibuprofen and naproxen for pain and fever in children, especially when combined with salicylate, appears to have resulted in a greater rate of gastric ulceration and erosions (7).

Acute bleeding can be classified as occult, overt, or massive. Massive bleeding (e.g., variceal bleeding) is the most dramatic

presentation and is usually accompanied by some degree of hemodynamic compromise.

DIFFERENTIAL DIAGNOSIS

A thorough history and clinical examination can usually lead to the diagnosis. Most patients presenting to the ED are stable yet, the differential diagnosis GI bleeding is large (**Tables 229.1** and **229.2**). The most important initial step is to determine whether the bleeding is of upper or the lower GI tract origin. The easiest method is to atraumatically insert a small, soft, nasogastric tube and perform a gastric lavage with tap water or normal saline at room temperature. Normal saline at room temperature (not chilled or "iced") should be used as the lavage fluid to avoid hypothermia, especially in infants or young children who are more prone to heat loss (8). If blood is not evident in lavage, it is unlikely the bleeding originates from above the ligament of Treitz.

The differential diagnosis of suspected GI bleeding in children is generally divided by age: (1) neonates to 1 month of age, (2) infants 1 month to 2 years, (3) preschool children 2 years to 5 years, and (4) school-aged children over 5 years. While some items in the age-specific differentials may overlap, there are unique causes of GI bleeding in each of these groups.

Newborn (0 to 1 Month)

Most causes of bleeding in neonates are never identified, since most bleeding is mild and stops spontaneously between 24 and 48 hours of life. Significant upper GI bleeding is more likely in neonates with sepsis, an intracranial lesion, or other major illness, in the form of stress ulcers or hemorrhagic gastritis. Hematemesis may also result from hemorrhagic disease of the newborn (vitamin K deficiency) or congenital bleeding disorders such as hemophilia, congenital thrombocytopenia, or the swallowing of a mixture of amniotic fluid and maternal blood (swallowed blood, however, may also manifest as lower GI bleeding). Swallowed maternal blood in breast-fed infants may come from a cracked nipple. The adult hemoglobin in

these cases can be easily differentiated from upper GI bleeding of patient origin (which will be fetal hemoglobin) using the Apt–Downey test (adding sodium hydroxide to a blood sample). Fetal hemoglobin resists alkaline degradation remaining pink whereas adult hemoglobin turns a brownish color (12).

Anal fissures and local trauma are the most common causes of rectal bleeding in the first month of life. However, both NEC and enterocolitis due to Hirschsprung disease (see Chapters 228 and 230) may present with occult or overt rectal bleeding. NEC is more common in preterm infants but may also be seen in the stressed term infant. Bilious vomiting, abdominal distention, and rectal bleeding are the most common clinical features and may also be due to surgical emergencies such as midgut volvulus. The finding of air in the bowel wall (pneumatosis intestinalis) on an abdominal radiograph is pathognomonic for NEC. While NEC is extremely rare relative to anal fissures clinicians should document pertinent negatives favoring a more benign anal fissure over more serious etiologies such as NEC.

Infant (1 Month to 2 Years)

In the infant upper GI bleeding is frequently caused by esophagitis, gastritis, or stress ulcers. Congenital malformations, such as duodenal web, while more likely to present in the newborn period, can present after the first month of life.

Lower GI bleeding is most commonly due to anal fissure and allergic colitis. Considerations should also include anorectal lesions, such as juvenile polyps (5). Intussusception, which may occasionally present with currant jelly stools, is most common in infants 7 to 12 months old (see Chapters 228 and 270). Infectious colitis is usually secondary to species of *Salmonella, Shigella, Campylobacter jejuni, Yersinia enterocolitica,* and *E coli* 0157:H7 (4) (see Chapter 224). *Clostridium difficile* infections are not always associated with recent antibiotic use and should therefore also be considered (4). In very limited circumstances other organisms that could be considered include *Aeromonas hydrophila* and *Entamoeba histolytica* (4). In

children with the acquired immunodeficiency syndrome (see Chapter 279), GI bleeding due to opportunistic infections such as cytomegalovirus should also be considered in the differential diagnosis (13).

Preschool (2 to 5 Years)

Anal fissures, infectious enteritis, and juvenile polyps are the most frequent causes of lower GI bleeding in the preschool age group. These polyps are usually solitary and benign and can often be felt on rectal examination (5). Massive GI bleeding from Meckel diverticulum is sometimes seen in preschool children. Infectious enterocolitis from agents similar to those described for the infant may also present with bloody stools. Multisystem diseases such as hemolytic–uremic syndrome and Henoch–Schönlein purpura are less common causes of bloody stools (see Chapter 287).

Varices in both the upper and the lower GI tracts can lead to massive, life-threatening hemorrhage in the appropriate patient population. Two-thirds of patients with portal hypertension sustain bleeds before 5 years of age, and 85% do so by age 10 years. On physical examination, other signs of portal hypertension or liver disease, such as splenomegaly, hepatomegaly, and dilated abdominal veins are present (14). Foreign body ingestion, although uncommon, should also be considered as a cause of upper GI bleeding (see Chapter 273).

School Age (Over 5 Years)

Anal fissures and juvenile polyps account for the majority of cases of lower GI bleeding. Intestinal lymphonodular hyperplasia of childhood has a peak incidence between 6 and 10 years; inflammatory bowel diseases (e.g., Crohn disease and ulcerative colitis) have a peak incidence in children over 5 years (15).

Esophagitis, gastritis, and peptic ulcer disease account for most cases of upper GI bleeding in school age children. Acute erosions of the gastric mucosa may occur after any major physiologic stress, such as trauma, shock, burns, or sepsis. Peptic ulcer disease may be

either primary or secondary to medications such as those used in patients with cystic fibrosis (e.g., corticosteroids and nonsteroidal anti-inflammatory agents). The possibility of occult oral ingestion of illicit drugs (e.g., cocaine) or iron tablets should be considered in cases of unexplained shock and hemorrhagic diarrhea (15).

ED EVALUATION

If the patient presents with signs and symptoms of cardiovascular compromise, immediate attention to restoring intravascular volume is necessary (see Chapters 217 and 219). Usually, however, the evaluation can be done in less urgent manner, beginning with a thorough history and physical examination. Under these circumstances, the emergency physician's initial step is to determine the site and magnitude of bleeding and whether it is ongoing.

Important elements of the history and physical examination are outlined in Table 229.3. A nasogastric tube should be inserted and fluid aspirated, unless a distal source is obvious. A positive aspirate for blood almost certainly indicates that the site of bleeding is proximal to the ligament of Treitz. However, a negative aspirate does not exclude an upper GI bleeding site beyond the pylorus.

TABLE 229.3
History and Physical Examination for GI Bleeding

History

Bleeding (duration, quantity, color, rectal vs. oral)
Associated abdominal pain
Vomiting/diarrhea
Medication history (e.g., aspirin, NSAIDs, steroid, alcohol)
Illicit drugs (e.g., cocaine)
Systemic diseases
Family history (e.g., bleeding disorder)
Social history

Physical Examination

Vital signs
Site of bleeding (nose, mouth, outside GI tract)
Acuity or chronicity
Anthropometric data
Cutaneous signs (e.g., spider nevi)
Abdominal tenderness/mass
Hepatomegaly
Splenomegaly
Anorectal examination

In most cases, the cause of bleeding is evident, but before beginning an expensive and possibly invasive workup, clinicians should confirm whether the patient is actually passing blood. Many foods and medications (e.g., tomato or cranberry juice, flavored gelatin, Kool-Aid, red licorice, ampicillin, rifampin, iron, and bismuth preparations [Pepto-Bismol]) can give stools a bloody appearance or a positive test for blood (2). In most hospitals, guaiac benzidine or benzidine derivative test pads (Hemoccult or Hematest) are used to detect blood. These tests use a hydrogen peroxide developer and are based on the peroxidase activity of hemoglobin and its derivatives. In the presence of hydrogen peroxide, these substances catalytically oxidize substrates such as guaiac or benzidine. The oxidation produces a color change in the substrate, indicating a positive test. However, false-negative results can be obtained if the patient has ingested large doses of ascorbic acid or if intestinal bacteria have degraded the hemoglobin to porphyrin. False-positive results can be seen if the patient has eaten

rare red meat or peroxidase-containing fruits and vegetables such as broccoli, radishes, cauliflower, cantaloupe, or turnips. The HemoQuant test, appears to be more sensitive and less prone to erroneous results (16).

Radiographic and nuclear imaging studies are rarely necessary in the ED. A plain abdominal x-ray may be useful if a foreign body ingestion, bowel perforation, or a bowel obstruction is suspected. Ultrasonography is indicated when intussusception, liver disease, portal hypertension, or vascular anomalies are suspected (10,11).

Laboratory studies (Table 229.4) should include a complete blood count with platelet and reticulocyte counts and a coagulation profile. An elevated eosinophil count signifies milk allergy or parasitic infestation. If bleeding is severe, blood should also be sent for a crossmatch. The BUN/Cr ratio is often used as an indicator of a source of bleeding in the upper GI tract and may provide an estimate of the severity of blood loss. An elevated BUN level is more likely to be associated with an upper than a lower GI bleed (9,17). Hepatic and renal function tests should be obtained. If an infective cause is suspected, stool should be examined promptly for fecal leukocytes, aerobic, and anaerobic cultures, and microscopy for ova and parasites (4,18).

TABLE 229.4
Laboratory Studies

Blood count: CBC with reticulocyte count
Coagulation profile: platelet count, prothrombin time, partial thromboplastin time, fibrinogen
Hepatic profile: bilirubin, SGPT, SGOT, albumin, alkaline phosphatase
Renal profile: Blood urea (BUN), creatinine (Cr), BUN/Cr ratio
Blood bank: type and crossmatch
Stools: Guaiac test, leukocytes, aerobic and anaerobic stool cultures, *C difficile* antigens, microscopy for ova and parasites

Plain radiography and sonography are noninvasive and minimally distressing and may give definitive information, such as a classic appearance of multiple short fluid levels in the abdomen in a

neonate with volvulus, or the appearance of an intraluminal mass on sonography with intussusception. If intussusception is suspected but the ultrasound is equivocal or inconclusive, an abdominal computed tomographic (CT) should be performed to evaluate for a rare form of intussusception known as small bowel intussusceptions disease which is usually ileal (19).

If the source of bleeding is not obvious after initial testing, more detailed evaluation, including endoscopy and complex radiographic procedures, may be necessary. However, most of these will not be conducted as part of the ED workup. In children with a positive nasogastric aspirate, endoscopy within the first 24 hours can determine the source of upper GI bleeding in 90% of cases. Emergency endoscopy in children has shown that the most common causes of bleeding are esophagitis, esophageal varices, gastritis, and duodenal ulcers (20, 21). Endoscopy is especially necessary in children with a history of esophageal varices, because the source of bleeding may be from other lesions. Upper GI barium studies are less accurate than endoscopy and may interfere with subsequent endoscopic examination.

Both endoscopy and barium studies may fail to determine the source of bleeding in patients with massive bleeding (bleeding greater than 0.5 mL/min, renders endoscopic examination of limited use). In these patients, arteriographic examination or nuclear scans (preferred by some clinicians due to lower complication rates (22)) of the superior and mesenteric arteries and the celiac axis may reveal a common cause of bleeding or, some less frequent causes such as hepatic artery aneurysm, traumatic hematobilia, arteriovenous malformation or hemangioma.

If the nasogastric aspirate does not contain blood, a rectal examination and colonoscopy can identify the source of rectal bleeding in 80% of cases. Additional studies are needed to identify the other 20%. Dark blood mixed with stool, in the absence of abdominal pain or diarrhea, may indicate Meckel diverticulum, intestinal duplication, or right-sided colonic polyps. A bleeding Meckel diverticulum is the cause in 80% of cases and can often be diagnosed by a nuclear medicine scan. Colonoscopy and, ultimately,

an air-contrast barium enema should be performed if the scan is inconclusive.

KEY TESTING

- Nasogastric aspiration to determine if source of bleeding is proximal to the ligament of Treitz
- Apt test in neonates or infants who may have swallowed maternal blood from cracked nipples
- CBC, PT, INR, and type and screen in appropriate patients with moderate to severe bleeding
- BUN and creatinine, liver function tests
- Plain x-ray of the abdomen for evidence of foreign body, bowel perforation, or pneumatosis
- Ultrasound for intussusception, or evaluation of portal hypertension
- Stool studies for infectious bloody diarrheas

ED MANAGEMENT

Assessment of Cardiovascular Status

Management depends on the child's clinical status and the severity and site of bleeding (Fig. 229.1).

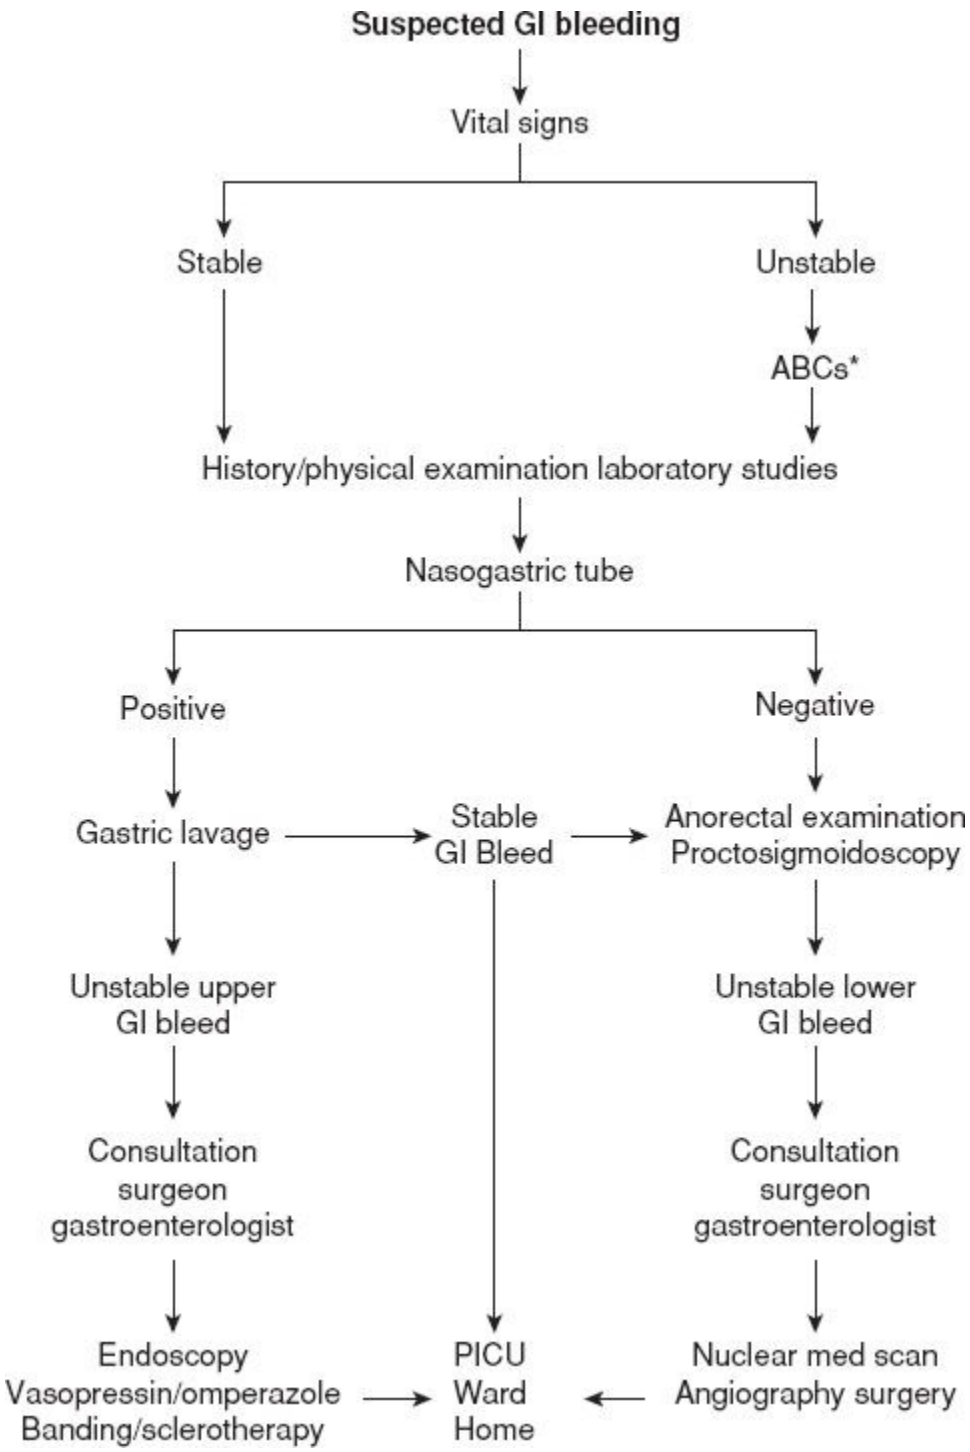

FIGURE 229.1 Flow diagram of suggested Management of GI bleeding in the ED ABCs (Airway Breathing Circulation) include attention to respiratory status (may include endotracheal intubation) and cardiovascular support (include vascular access, crystalloid, FFP, platelets, and blood infusions).

Initial management is based on the child's condition, including factors such as age, source, rate, and amount of bleeding, and associated medical illnesses. Assessment of cardiopulmonary status and prompt attention to any derangements should be a priority (see Chapters 217 and 219). Oxygen administration and venous access, followed by fluid boluses of crystalloids (20 mL/kg lactated Ringer or normal saline), are mandatory, particularly if the patient has signs of volume compromise (anxiety, tachycardia, weak pulses, delayed capillary refill, hypotension, tachypnea). Additional fluid boluses should be given as determined by frequent reevaluations. A nasogastric tube is then placed in the stomach, and lavage with tap water or room temperature saline should be started.

Occult Bleeding

In the stable child with occult bleeding, management is geared toward establishing a diagnosis and excluding serious conditions. Investigations are dictated by the history and physical examination, but most tests, including cultures, radiologic or nuclear medicine scans, and endoscopy, can be performed on an outpatient basis. The cause of occult upper GI bleeding in children is often not from the GI tract. Although anal fissures account for most cases of occult blood in stools, physicians should always consider less benign causes (e.g., NEC or intussusception) in the ill appearing neonate or infant. Occult bleeding may also presage other serious events, such as Meckel diverticulum.

Overt Bleeding

Administration of crystalloids (normal saline or Ringer lactate) to restore intravascular volume is the management priority. Samples for urgent type and crossmatch should be sent or O-negative blood made immediately available. The child who has lost 10% to 20% of his or her blood volume does not necessarily require blood replacement, provided the bleeding has stopped. If, after 20% of the blood volume has been replaced by crystalloid and bleeding continues then transfusion will likely be necessary. The child's age

and physical condition may also dictate the need for blood; for example, children with heart and chronic lung disease may require transfusion earlier. Platelets, fresh frozen plasma, or vitamin K (1 mg per year of age, up to 10 mg) is given to correct an identified coagulopathy. Consideration should be given to the use of recombinant factor VII therapy (60 to 90 μgm/kg per dose, intravenously) in cases of bleeding due to severe coagulopathy from DIC or an unknown cause (23). In the neonate suspected of vitamin K deficiency, vitamin K (1 mg) is given intramuscularly. H_2 blockers are best given intravenously by continuous infusion. Ranitidine is the recommended agent at a dosage of 1.5 to 6 mg/kg/d intravenously, depending on the patient's age. High-dose antisecretory therapy with an intravenous pump inhibitor such as omeprazole, has been shown to be relatively safe in the treatment of children with GI hemorrhage (24). Acid suppression therapy with antacids, H_2 blockers, sucralfate, and a proton pump inhibitor, may be administered although there are no studies demonstrating clear benefits in children.

Massive Bleeding

Aggressive fluid resuscitation and administration of blood components is the usual management, however, in some cases, endotracheal intubation, to secure the airway and decrease the work of breathing, is needed in a patient with low cardiac output. Endotracheal intubation allows adequate sedation without the risk of hypoventilation or aspiration, and also facilitates endoscopy (see Chapter 218). Continuous monitoring of vital signs, urine output, and oxygen saturation are essential. Central venous catheter placement, although not mandatory, may be helpful for vascular access and for monitoring intravascular volume status.

Management of children with massive variceal bleeding from portal hypertension includes NG tube placement, correction of coagulopathy with platelets, vitamin K and FFP, intravenous vasopressin (0.33 U/kg bolus and infusion of 0.2 U/1.73 m^2/min infusion), octreotide infusion (1 to 5 μg/kg/hr), and variceal

injection, or ligation via endoscopy (14). In life-threatening GI bleeding, consideration should also be given to the use of recombinant activated factor VII (23).

Massive bleeding can also occur in children with Meckel diverticulum; these patients also require aggressive resuscitation. Following cardiovascular stabilization, the site of bleeding can be confirmed by a nuclear scan or by arteriography. If massive bleeding precludes stabilization, immediate laparotomy may become necessary.

CRITICAL INTERVENTIONS

- Assessment of cardiorespiratory status—determine if shock or respiratory distress is present and resuscitate appropriately
- If the patient has a massive GI bleed, start two large bore IVs. Send blood for type and crossmatch, and coagulation factors
- Quick history and physical examination—determine source of bleeding
- Pass a NG tube and perform gastric lavage if the source is not obvious or is suspected to be from the upper GI tract
- Check stools to see if blood is present

DISPOSITION

Conditions requiring urgent surgical evaluation include volvulus, vascular malformations, and NEC in the neonate. Some cases of GI bleeding from stress ulcers, variceal bleeding, or intussusception may also require urgent surgical evaluation. Consultation with a pediatric gastroenterologist, pediatric surgeon, and/or pediatric intensivist may be necessary early in management. Panendoscopy to establish a specific diagnosis and to assess the rapidity of bleeding, the risk of rebleeding, and, the administration of definitive therapy may be required (20,21).

During interhospital transfer, the child with GI bleeding is prone to compromise the cardiorespiratory system. Oxygenation and vascular access with the administration of crystalloid are priorities if there is evidence of vascular compromise. Continuous monitoring to

ensure an adequate airway and stable vital signs is mandatory. Although personnel skilled in advanced pediatric life support should accompany the child, attention to stabilization before transport should minimize the need for interventions during transport.

Common Pitfalls

- Assuming the colored material is blood. Many foods and medicines can give secretions or stools a bloody appearance.
- Failing to perform an Apt test on a neonate's gastric contents or stool to rule out swallowed maternal blood.
- Using the wrong-sized nasogastric tube. Smaller bore tubes may be adequate for assessing bleeding, but not for removing clots.
- If the nasogastric aspirate does not sample duodenal contents, or if bleeding is intermittent, a false-negative aspirate may result.
- A traumatically placed nasogastric tube may yield a false-positive aspirate and cause distress to the patient. Iodine, supplemental iron, and ingestion of red meat may cause false-positive results.
- A normal hemoglobin level does not exclude significant, rapid GI bleeding.
- A normal or increased blood pressure in children does not exclude hypovolemia.
- Performing a barium study before endoscopy.
- Not considering sexual abuse as a cause of anal fissures.
- Failing to consider nonorganic causes (e.g., Munchausen syndrome by proxy) of GI bleeding.

CHAPTER 230 Constipation

Le N. Lu and Dewesh Agrawal

Although there are relatively few situations in which disorders of bowel control are truly emergent in children, parental concerns about constipation frequently result in emergency department (ED) visits. Emergency physicians should be able to distinguish abnormal from normal bowel habits and advise concerned parents about the developmental process of bowel control, including normal stooling patterns.

In the pediatric population, a single definition of constipation has not been agreed upon. Although many parents focus on the length of time between bowel movements, a determination of normal should encompass stool consistency and the ease with which the stool is passed. The North American Society of Pediatric Gastroenterology, Hepatology, and Nutrition (NASPGHAN) defines constipation as a delay or difficulty in defecation present for 2 or more weeks sufficient to cause significant distress to the patient (1). The epidemiology and clinical scenarios commonly associated with constipation vary with age. In infants and toddlers, constipation occurs equally in boys and girls. In older, prepubertal children, constipation is more common in boys, with a male-to-female ratio of 3:1. During adolescence, this ratio reverses, with constipation being three times more common in girls (2).

There is a wide variation of “normal” stool patterns. The normal newborn passes a meconium stool within the first 48 hours of life and a mean of four stools per day during the first week of life. Some breast-fed newborns may pass a small, loose stool after each feeding, whereas others may not produce stools for several days.

The frequency of stooling gradually declines to a mean average of 1.7 stools per day by age 2, approaching the adult mean of 1.2 stools per day by age 4. In children beyond infancy, the normal frequency ranges from one stool every other day to three per day (1,2). The color of stool changes from thick tarry meconium in the first few days of life to yellow mustard-colored stools ("milk stools") a few days after the mother's milk comes in. Formula-fed babies may have tan, green, or yellow stools.

CLINICAL PRESENTATION

A newborn infant discharged from the hospital before reaching 48 hours of age is brought to the ED with a history of constipation, progressive abdominal distention, and vomiting. This disorder may be caused by imperforate anus, anal stenosis, meconium plug syndrome, meconium ileus, or Hirschsprung disease.

Many healthy infants cry, strain, grunt, and turn red or purple in the face for 5 to 10 minutes during normal bowel movements. Distraught parents, erroneously interpreting this behavior as a sign of constipation, may present to the ED seeking relief for the infant's perceived abdominal pain. This behavior is caused by the infant's immature coordination between abdominal muscle contraction and relaxation of the pelvic floor (2,3). As long as the stools are soft in consistency and normal in appearance, parents should be reassured that this condition generally resolves spontaneously (4). Rectal stimulation may be counterproductive, and routine laxatives and enemas are unnecessary and should be avoided.

Constipation in children older than 24 months is far less likely to be serious or life-threatening, yet is a source of great anxiety and frustration for some parents. These children usually present with periumbilical abdominal pain, distension, anorexia, and irritability. Upon questioning, a history of similar episodes of abdominal pain and marked symptomatic improvement after a large bowel movement may be elicited. Occasionally, parents describe actions such as squirming, standing on toes, rolling into fetal position, or other ritualistic behaviors, which are often misinterpreted as

straining to defecate, but are actually attempts to withhold stool and relieve the urge to defecate. The association of pain with defecation leads to the cycle of retention and subsequent avoidance of defecation, and increasing fecal mass with further degrees of retention (4). This situation may be caused or complicated by the development of anal fissures, which cause pain with the passage of each large stool. Eventually, the fecal mass may become impacted, and unformed liquid stool may leak around the impaction, resulting in overflow incontinence and soiling of undergarments. A lower abdominal mass may be found on palpation, and a rectal examination may reveal fecal impaction (2). In addition, there is an association between stool retention behavior and dysfunctional urinary voiding which may lead to renal tract dilation and urinary tract infection (5–7).

DIFFERENTIAL DIAGNOSIS

The major causes of constipation in children can be divided into two broad categories: functional and organic (Table 230.1). Functional constipation is defined as constipation without objective evidence of a pathologic condition (1). Although organic causes are responsible for fewer than 5% of cases, failing to diagnose these may have serious consequences. Findings associated with an organic etiology for constipation include delayed growth, delayed passage of meconium, urinary incontinence or bladder disease, hematochezia, melena, constipation from birth, fever, vomiting, or an empty rectum on physical examination. In the newborn, failure or delay in passing meconium is of organic etiology until proven otherwise. Anatomic malformations and congenital intestinal disorders are more likely to present in infancy than at a later age, but nonorganic causes of constipation predominate at all ages (2,8). Findings supporting a functional etiology include stool withholding behavior, good response to conventional laxatives, or onset of symptoms coinciding with dietary changes, toilet training, or painful defecation. Beyond the immediate newborn period, constipation tends to be less emergent in nature, and most cases have either a

functional or dietary cause (8,9). In a child presenting with a chief complaint of abdominal pain, functional constipation should be a diagnosis of exclusion after all pathologic causes of abdominal pain have been ruled out.

TABLE 230.1
Differential Diagnosis of Constipation

Functional
Developmental: cognitive handicaps, attention deficit disorders
Situational: coercive toilet training, school bathroom avoidance, sexual abuse
Reduced stool volume and dryness: low-fiber diet, dehydration, malnutrition
Organic
Anatomical: imperforate anus, anal stenosis, anal stricture, anteriorly displaced anus, pelvic mass, rectal abscess
Metabolic/endocrine: hypothyroidism, hypercalcemia, hypokalemia, cystic fibrosis, diabetes mellitus, gluten enteropathy
Neurologic: Hirschsprung disease, spinal cord abnormalities, neuronal dysgenesis, tethered cord, neurofibromatosis, cerebral palsy
Muscular: prune belly, gastroschisis, myopathy, infant botulism
Connective tissue disorders: scleroderma, lupus, Ehlers–Danlos syndrome
Drugs: opiates, phenobarbital, sucralfate, antacids, anticholinergics, antidepressants
Other: cow's milk intolerance, botulism, lead toxicity, vitamin D intoxication

Adapted from Baker SS, Liptak GS, Colletti RB, et al. Evaluation and treatment of constipation in infants and children: Recommendations of the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition. *J Pediatr Gastroenterol Nutr.* 2006;43(3):e1–e13.

Imperforate anus is usually diagnosed by inspection, which reveals no anal opening. In anal stenosis, the anus appears small with a central black dot of meconium.

Meconium plug syndrome is strongly related to Hirschsprung disease and presents with little or no meconium in the newborn period and with progressive signs of intestinal obstruction. Hirschsprung disease is the cause of up to 25% of neonatal intestinal obstructions. Gentle digital examination may produce passage of a dry, hard plug of meconium. Hirschsprung disease typically presents with an empty rectal vault and a long, sleeve-like anal canal around the examining finger. It is more common in boys and is occasionally

associated with Down syndrome. More advanced cases may present in early infancy with enterocolitis, sepsis, fever, vomiting, and diarrhea that can progress to toxic megacolon. Newborns who are not diagnosed may present later in childhood with chronic constipation, abdominal distention, and failure to thrive. In addition to a failure to pass meconium within the first 48 hours of life, these patients experience ongoing constipation and small-diameter (ribbon-like) stools.

Meconium ileus occurs when meconium becomes inspissated and obstructs the distal ileum. It is virtually pathognomonic of cystic fibrosis and precedes the respiratory symptoms of the disease, which are usually absent in the newborn. The clinical picture is usually dominated by the bowel obstruction and its associated complications including perforation, peritonitis, or volvulus.

Botulism is a rare but potentially life-threatening neuroparalytic syndrome from the action of the neurotoxin produced by *Clostridium botulinum*. Although the disease presentation and severity varies, the initial presentation may simply involve constipation, followed shortly by weakness, feeding difficulties, respiratory difficulties, descending paralysis, drooling, anorexia, and a weak cry.

The clinical manifestations of lead poisoning vary with lead level, the age of the exposed individual, and the acuity of poisoning. Lead colic includes sporadic vomiting and intermittent abdominal pain. Constipation may occur with blood lead levels >60 μg/dL (2.9 μmol/L).

ED EVALUATION AND MANAGEMENT

The Constipation Subcommittee of NASPGHAN has developed a clinical practice guideline for the evaluation and management of constipation (1). A history and physical examination often provide the diagnosis without requiring further studies in the ED (8). Information regarding the time after birth of the first bowel movement, length of time the condition has been present, frequency of bowel movements, consistency and size of stools, presence of pain and blood, and toilet use habits (if applicable) should be obtained.

Dietary habits, medications, associated fever, abdominal distention, anorexia, vomiting, weight loss, and poor weight gain should be assessed. Physical examination should include abdominal palpation for masses, especially fecal masses in the left lower quadrant; inspection of the perineum and perianal area for fissure, anterior displacement, or stenosis; and inspection of the sacrum and lower extremity neurologic examination for signs of myelodysplasia. Gentle rectal examination with a well-lubricated fifth digit should be attempted, but not forced on an unwilling child, to assess perianal sensation, anal tone, rectal size, presence of an anal wink, and the amount and consistency of stool within the rectum.

Exhaustive laboratory and radiographic investigation is not usually required in the ED (8). It is recommended that a test for occult blood in the stool be considered in all infants with constipation and in any child who also has severe abdominal pain, failure to thrive, intermittent diarrhea, or a family history of colon cancer or colonic polyps. If the history is chronic, a urine culture should be obtained to avoid missing an occult urinary tract infection. If the rectal examination reveals the presence of large amounts of stool in the rectal vault an abdominal radiograph is not necessary to diagnose fecal impaction and is in fact a redundant test. Occasionally, a plain abdominal radiograph may be helpful in confirming the diagnosis when the history or physical examination are confusing or inconclusive, or other causes of acute abdominal pain have been ruled out.

The first step in managing constipation is education of the child and family. Disimpaction may be necessary prior to initiation of maintenance therapy. Disimpaction can be accomplished by using oral medications (Table 230.2), rectal medications, or a combination of the two. All approaches have been determined to be effective in clinical trials (1,10–13) and the individual approach should be discussed with the child and family. Rectal disimpaction may be performed in older children using sodium phosphate soda enemas, saline enemas, mineral oil enemas, milk and molasses enemas, or polyethylene glycol (PEG, MiraLAX) oral solution (10–13). Although an enema may provide more immediate relief of symptoms than

polyethylene glycol, they are equally effective (10,12). Cathartics, suppositories (other than small glycerin suppositories), and enemas should generally be avoided in infants (1). The use of soap suds, tap water, and magnesium enemas is not recommended because of potential toxicity; tap water enemas have been associated with acute hyponatremia, seizures, and death (14).

TABLE 230.2
Oral Disimpaction Therapy

Mineral oil[a]: 1–4 mL/kg/d divided daily or bid
Milk of magnesia: 1–3 mL/kg/d divided daily or bid
Lactulose: 1–3 mL/kg/d divided daily or bid
Polyethylene glycol (MiraLAX):
Disimpaction: 1.5 g/kg/d × 3–6 d (maximum 100 g/d)
Maintenance: 1 g/kg/d divided bid (maximum 17 g/d; prepared by mixing 1 capful of powder in 8 oz of liquid)
Sorbitol: 1–3 mL/kg/d divided BID (70% solution)
Senna: 2–6 yrs old, 2.5 to 7.5 mL daily; 6–12 years old, 5–15 mL daily (syrup)
Bisacodyl: 5–10 mg daily

[a]Contraindicated in infants and children at risk for aspiration.
bid, twice daily.

Maintenance therapy of constipation, best managed by the child's primary care clinician, consists of dietary changes, behavioral modification, and laxatives (1,8). Dietary management includes increasing fluid intake and adding bulk and fruits, such as prunes or plums, to the diet. Barley malt extract (Maltsupex) or corn syrup (Karo) can be safely recommended for infants in a dosage of 5 to 10 mL two to four times daily, added to formula, juice, or food. Behavioral modification for the older child with stool withholding includes regular toilet sitting (especially immediately after meals to harness the gastrocolic reflex), stool diaries, and reward systems. Parents and children should be educated about stool-withholding behaviors and rituals. Although there is some evidence that increased fiber may be more effective than placebo for chronic childhood constipation, there is insufficient evidence for other

nonpharmacologic interventions such as prebiotics, probiotics, increased fluid intake, behavioral therapy, and other forms of alternative medicine (15,16). In older infants and toddlers, maintenance therapy may include milk of magnesia, mineral oil, lactulose, or polyethylene glycol (MiraLAX). A systematic review failed to find sufficient evidence to recommend any one laxative or dietary treatment over another (15). Polyethylene glycol and milk of magnesia are equally effective in the long-term treatment of children with constipation and fecal incontinence (8,17,18). Docusate or senna extract can also be safely used daily in older children.

Management of anal fissure includes frequent, gentle, thorough cleansing of the anus and liberal lubrication with petroleum jelly. A stool softener must be used, and a topical anesthetic ointment such as dibucaine may be necessary (19). Aggressive care of the simple fissure is necessary to prevent a pain-retention cycle from becoming established.

KEY TESTING

- Careful complete history and physical examination.
- Abdominal radiograph may be indicated in patients with no stool in the rectal vault and when the history and physical are inconclusive.
- Urinalysis and culture in patients with history of chronic constipation to evaluate for occult UTI

CRITICAL INTERVENTIONS

- History and physical examination are essential to evaluating a child with constipation.
- All newborns presenting with constipation should be evaluated for serious or life-threatening etiologies.
- Aggressively treat anal fissures to break the pain-retention cycle.
- Provide parent education regarding behavior modification and the importance of regular follow-up with a primary care provider.

DISPOSITION

Consultation for routine constipation is unnecessary. Infants with suspected Hirschsprung enterocolitis or bowel obstruction should be expeditiously referred to a pediatric surgeon. Older children with suspected Hirschsprung disease should be referred to a pediatric gastroenterologist or pediatric surgeon. Children with chronic constipation with or without encopresis should be referred to a pediatrician for long-term management.

The following are indications for admission: (1) failure to pass meconium within the first 48 hours of life, (2) acute bowel obstruction, or (3) evidence of toxic megacolon complicating Hirschsprung disease. Occasionally, complicated disimpaction and the initiation of a therapeutic regimen for chronic constipation with encopresis may require admission, but this is rare.

Common Pitfalls

- In the newborn or young infant, failing to entertain a broad differential diagnosis which should include Hirschsprung disease, necrotizing enterocolitis, congenital gastrointestinal malformations, and infant botulism.
- In older children with marked stool retention, misinterpreting withholding behaviors as straining to defecate.

CHAPTER 231
Cough

George Waterman

CLINICAL PRESENTATION

Cough is a frequent complaint for children who present to the emergency department (ED). Coughing is a vital reflex for clearing secretions from the airway and for protection from inhalation of foreign matter. Although in many cases cough is caused by a self-limited viral illness, it is a nonspecific symptom requiring a systematic approach to exclude serious pathology (1).

DIFFERENTIAL DIAGNOSIS

There are multiple possible etiologies for coughing in a child. Selected causes will be discussed in more detail. A more comprehensive list can be found in Table 231.1.

TABLE 231.1
Causes of Cough in Children (2)

Congenital Abnormalities	Inflammatory/Environmental
Vascular Ring	Allergic rhinitis
Laryngomalacia	Asthma
Tracheomalacia	Smoke exposure
Tracheoesophageal fistula	Foreign body aspiration
Infectious	**Other**
Viral upper respiratory illness	Tourette syndrome
Sinusitis	Foreign body in ear canal
Bronchitis	Gastroesophageal reflux
Croup	Medications
Pertussis	Cardiac
Bronchiolitis	
Pneumonia	

The most common cause of childhood cough is viral upper respiratory infection (3). These children are typically well appearing and often exhibit rhinorrhea on examination. Coughing associated with these illnesses is expected to resolve within 3 weeks (4).

Upper airway cough syndrome is a common cause of cough due to irritation of the upper airway from postnasal drip due to viruses or allergens. This is a frequent cause of acute cough in children with common colds (5).

Asthma may sometimes present with coughing as the predominant symptom (6). Supportive evidence of a diagnosis of asthma includes a personal or family history of atopic symptoms such as eczema or allergic rhinitis (7).

Coughing has been cited as a common symptom in many cases of foreign body aspiration (8). A foreign body must be ruled out if a persistent cough follows a choking episode.

Cough associated with fever, tachypnea, and rales on auscultation is a concern for pneumonia. These children are often ill appearing with increased work of breathing. *Streptococcus pneumoniae* is the most common bacterial pathogen, but other likely possibilities include viruses, *Mycoplasma pneumoniae,* and *Chlamydia pneumoniae* (see Chapter 265) (9).

Bordetella pertussis should be considered if cough is prolonged (>3 weeks) in duration, if it is paroxysmal, and if associated with

posttussive emesis (10). Despite widespread vaccination, the incidence of pertussis has been on the rise for the past 15 years (see Chapter 262) (11).

Chronic cough in infants and children is often caused by asthma or recurring viral upper respiratory infections. Anatomic abnormalities, such as anomalies causing compression of the airway, can lead to persistent or recurrent symptoms. These include vascular rings, coarctation of the aorta, hemangiomas, pulmonary sequestrations, and masses in the mediastinum. Tracheoesophageal fistula should also be suspected in infants with repeated episodes of aspiration or in those with features of VACTERL association (a group of abnormalities that may include *V*ertebral defects, *A*nal atresia, *C*ardiac defects, *T*racheo-*E*sophageal fistula, *R*enal anomalies, and *L*imb abnormalities) (12).

Tuberculosis is a consideration in children who have a history of traveling to endemic areas, particularly if there are associated symptoms of weight loss, hemoptysis, and night sweats (13).

DIAGNOSTIC APPROACH

The examination of any patient with a cough will begin with evaluation of the airway and of the effectiveness of breathing and circulation. The airway should be evaluated for patency, and breathing for accessory muscle use and abnormal sounds. A complete set of vital signs including pulse oximetry should be obtained on arrival. If there is concern for increased work of breathing or hypoxemia, oxygen should be administered and the child should be kept in a position of comfort. Advanced airway equipment should be readily available for the child who does not respond to basic interventions. Children with severe croup or those with foreign bodies in the trachea may require intubation if they show signs of respiratory failure. Although rare in Western countries nowadays, if epiglottitis is suspected, intubation is ideally performed in the operating room. After initial stabilization as needed, a more detailed history and physical examination should be

initiated. In the majority of cases, this will be sufficient to arrive at a diagnosis. Important historical elements are listed in Table 231.2.

TABLE 231.2
Historical Elements

Age of onset of cough
Duration of cough
Characteristics and associated symptoms
Factors that improve/worsen cough
Past medical history including surgical procedures
Medications/allergies
Environmental exposure including travel history, trauma
History of choking prior to cough

The physical examination should begin with the overall appearance of the child while at rest. If possible, it may be useful to have a child sit in the caregiver's lap initially to assess for work of breathing while the patient is calm. Important findings to note on physical examination are listed in Table 231.3.

TABLE 231.3
Physical Examination

Overall appearance including body habitus
Work of breathing (retractions, grunting, nasal flaring)
Nasal discharge/swollen nasal turbinates
Allergic shiners/nasal creasing
Foreign material in ears/nose
Tonsillar hypertrophy
Heart murmurs
Breath sounds (wheezes, rales, stridor)
Organomegaly
Clubbing/cyanosis

A chest x-ray should be obtained if there is suspicion of a foreign body, significant respiratory distress, or concern for a bacterial etiology. If concern for foreign body persists despite

nonvisualization on x-rays, bronchoscopy should be arranged. Other testing to consider in selected cases of cough include viral assays, sputum culture, pulmonary function testing, and swallowing studies.

Treatment for cough is targeted to the underlying cause. If the etiology is viral, there is no evidence that over-the-counter medications are useful and they may in fact have harmful side effects (14,15). Bronchodilators or racemic epinephrine may be used in conjunction with steroids if indicated for bronchospastic symptoms or croup. Antibiotics should be reserved for children with a likely bacterial source and follow-up should be arranged to ensure that symptoms are resolving as expected.

CRITICAL INTERVENTIONS

Evaluation of the ABC's is the first priority in any patient with a cough, and is followed immediately by interventions needed for stabilization (e.g., nebulized medications, steroids). If signs of respiratory distress are present, cardiac and respiratory monitoring are indicated. Supplemental oxygen should be provided in patients who display increased work of breathing or hypoxia. If there is concern for aspiration of a nonradioopaque foreign body, bronchoscopy should be arranged.

DISPOSITION

Most children with cough may be discharged home if they do not have an oxygen requirement, are tolerating oral intake, and are not experiencing increased work of breathing. Other reasons to consider admission include the need for inpatient workup, outpatient antibiotic treatment failure, and concern for the parent's ability to care for the child. It is important to stress to families that coughing associated with routine viral illnesses can last up to several weeks and that the utility of over-the-counter cough suppressants is modest at best and may be harmful.

Common Pitfalls

- Failing to optimize the conditions for physical examination. Auscultation for breath sounds should take place with the child in a position of comfort prior to uncomfortable aspects of the examination.
- A child with continued symptoms of foreign body aspiration should not be discharged even if the chest x-ray is negative.
- Failing to establish close follow-up in children with pneumonia and in those going home with bronchodilators.
- Prescribing empiric antibiotics when there is not a likely bacterial source and use of over-the-counter antitussives.

CHAPTER 232 Shortness of Breath

Denis Pauze

Respiratory distress represents a compensatory response to impaired oxygen delivery to tissues, with or without decreased carbon dioxide elimination. The respiratory tract can be divided into two anatomic categories: (1) the lungs, or gas-exchange portion; and (2) the "respiratory pump," consisting of the thoracic cage, respiratory muscles, and neural pathways governing the system, Pathology involving any of these areas can present with signs and symptoms of respiratory distress. Other factors, outside the respiratory system, can also lead to shortness of breath, including myocarditis, supraventricular tachycardia (SVT), sepsis, and metabolic abnormalities such as diabetic ketoacidosis (DKA). Depending on the etiology of the respiratory compromise and the time until presentation to the emergency department (ED), these signs and symptoms may be obvious or subtle.

There are a number of differences between the pediatric and the adult patient that place children at greater risk for respiratory compromise. Infants and young children have a subglottic airway that is smaller and has less cartilaginous support, making it easier for obstruction to occur secondary to edema, secretions, constriction, or compression. Dynamic collapse of a partially obstructed airway, as seen in croup during inspiration, is an example of the consequences of a high-compliance airway (1). Children younger than 1 to 2 years of age may not have the anatomic pathways or "collateral ventilation" that allows aeration distal to an obstruction, thereby increasing the risk of atelectasis and ventilation–perfusion mismatching.

Because of the increased chest-wall compliance of the pediatric patient, compensatory diaphragmatic breathing may result only in distorting the rib cage as opposed to creating the necessary negative pressure to expand the lungs. The younger the child, the greater the pliability of the chest wall. This places the neonate at greatest risk for fatigue and respiratory failure.

In addition to anatomic differences, there are important physiologic differences. Hypoxemia and acidosis occur more rapidly in children with respiratory compromise because of their higher metabolic rate, which causes an increase in oxygen demand (1). Furthermore, tachypneic infants experience increased insensible losses in the form of exhaled water vapor. These losses become clinically significant as patients experience feeding difficulties in the face of progressive respiratory compromise.

CLINICAL PRESENTATION

The presentation of a child in respiratory distress varies, depending on the specific etiology, duration of illness, age, underlying medical conditions, and interventions prior to arrival in the ED.

Signs of respiratory distress can be separated into those that are visible and those that are audible (Table 232.1). Initially, simply observing a child and listening from afar (avoiding prolonged eye contact or use of a stethoscope) can provide critical information without creating anxiety or agitation, which may serve to worsen the patient's condition.

TABLE 232.1
Indicators of Actual or Possible Respiratory Compromise

Visual	Audible
Chest retractions	Cough
Abnormal behavior	Stridor
Altered mental status	Wheezing
Tachypnea/bradypnea	Grunting
Shallow/deep respirations	Abnormal voice or cry
Nasal flaring	
Head bobbing	
"See-saw" respirations	
Cyanosis	

Visual inspection begins with the child's subjective behavior. Normal behavior does not rule out pathology, but does indicate that the child is comfortable and needs no urgent intervention. When possible, children should be allowed to find their "position of comfort" to optimize oxygenation and ventilation; the demeanor and position assumed can be diagnostic. For example a quiet, serious child who prefers sitting upright in a sniffing position is a cause for concern and requires immediate assessment. Restlessness and irritability can be subtle clues to hypoxemia. Drooling or changes in phonation should also be considered an emergency until proven otherwise. Altered mental status can represent either generalized central nervous system (CNS) disease or hypercarbia, with or without hypoxemia.

The presence of either tachypnea or bradypnea is taken as evidence of respiratory compromise. It is important for clinicians to be familiar with the range of normal pediatric respiratory rates and to appreciate the wide range of "normal." In addition, fever, pain, and anxiety may result in an increased respiratory rate in the absence of primary pulmonary disease. Patients younger than 1 year of age have a median respiratory rate of 37–43, with a range from 22–66. Patients 2 to 3 years of age have a median range of 28, with ranges from 18–38. Respiratory rates in children 8 and above start falling in the adult range (2).

The best markers of respiratory distress are changes in the respiratory rate, character, and depth, rather than the number of breaths per minute measured at a fixed point in time. Shallow respirations are often seen in lower airway obstruction, and deep

respirations often represent central compensatory mechanisms in response to metabolic acidosis. Retractions may be seen in the supraclavicular, subcostal, and intercostal areas. Chest retractions begin subcostally with mild disease and progress upward as patient's condition becomes worse. Nasal flaring is sometimes a subtle sign that is more commonly present in infants and younger children and is associated with lower tract disease. Head bobbing with each breath and "see-saw" or "rocky" respirations, where the chest pulls in as the abdomen thrusts out, are signs of severe distress; the latter is an inefficient means of ventilation that can quickly lead to respiratory failure (1). Cyanosis usually correlates with a $PO_2 < 40$ and an arterial oxyhemoglobin saturation of $\leq 85\%$. Anemic patients can be acyanotic and profoundly hypoxic, making cyanosis an unreliable indicator of hypoxemia (1).

Certain indicators of respiratory distress can be heard without the use of a stethoscope. Persistent, forceful, nonproductive coughing may indicate a foreign body lodged in the upper airway, with the potential for complete obstruction. Stridor is a harsh, crowing sound occurring during inspiration (3) and commonly seen in the pediatric population. Stridor, produced by rapid, turbulent air flow through a narrowed area, signifies upper airway pathology. Wheezing represents expiratory obstruction of the lower airways. If heard without chest auscultation, wheezing indicates serious disease and the need for urgent intervention. Grunting, an end-expiratory sound, is produced by glottic closure during exhalation in an attempt to provide physiologic positive end-expiratory pressure (PEEP). Grunting indicates a disease process causing increased alveolar and/or interstitial fluid. An abnormal voice or cry, particularly if muffled in quality, should alert the clinician to possible upper airway disease and the need for prompt, nonthreatening evaluation. In the absence of visual and audible signs of respiratory distress, the likelihood of an infant or child having serious respiratory pathology requiring emergent intervention is small.

Neonates deserve special mention. Normally, neonates have respiratory rates of approximately 40 to 50 breaths/min. A

respiratory rate of 60 or more should usually be considered abnormal. Neonates with tachypnea may also exhibit grunting, stridor, accessory muscle use, and central cyanosis. On the other hand, neonates may present with irregular, but nonetheless normal, breathing patterns because of immature respiratory centers. Additionally, the neonate with shortness of breath may also have intermittent episodes of apnea, as seen with advanced RSV.

DIFFERENTIAL DIAGNOSIS

Determining the precise etiology of respiratory distress in the pediatric patient can be challenging; the differential diagnosis is substantial (Table 232.2). Clinicians must recognize the signs and symptoms of respiratory distress in a child and must be able to judge the degree of severity. In moderate to severe degrees of distress, a rapid assessment of the likely etiology is necessary so that appropriate therapy can be initiated. The most common etiologies include asthma, bronchiolitis, croup, and pneumonia, which are described in other chapters.

TABLE 232.2
Etiologies of Respiratory Distress

OTHER

Seizures
Cardiac failure
Cystic fibrosis
Metabolic acidosis
Vocal cord dysfunction
Congenital anomalies
Hypocalcemia

Age is an important factor in differentiating etiologies of dyspnea. Neonates are more prone to congenital diaphragmatic hernia, congenital lobar emphysema, bronchogenic cysts, and tracheomalacia, which may present within the first days or weeks of life. Other congenital anomalies, such as vascular rings or laryngeal webs, though uncommon, are additional potential etiologies of dyspnea in the neonatal period.

Stridor indicates some form of upper airway obstruction, and when it is associated with fever, one should suspect an infectious etiology. Croup classically presents between 6 months and 3 years of age with a history of a low-grade fever and upper respiratory infection (URI) symptoms for a few days, followed by the gradual onset of a barking cough, hoarseness, and stridor, with or without chest retractions (4).

In any child thought to have croup, the diagnosis of epiglottitis must also be considered. Epiglottitis may also be a life threatening cause of stridor, and can occur at any age. While epiglottitis was once common in the 3–8 year age range, the post vaccination era has shifted epiglottitis towards older patients. Today viruses, other

bacteria and different Hib serotypes make up the etiologic factors behind acute epiglottitis (5). On physical examination, the most common signs of epiglottitis have been reported to be stridor (88%), retractions (81%), and temperature $\geq 38^{\circ}C$ (85%); drooling (66%) and a preference for sitting (58%) are less common. The time course from the first clinical sign of epiglottitis to respiratory failure can be short, often less than 12 hours (6). Other early signs and symptoms of epiglottitis include “pain out of proportion to examination” and a child that is “not getting better with antibiotics.” In distinguishing between epiglottitis and croup in a child presenting with fever, stridor, and retractions, the importance of the history cannot be overemphasized. Drooling in the absence of spontaneous cough is the most specific indicator of acute epiglottitis.

Recurrent croup should be noted as a red flag. Approximately one-third of these children may have some type of anatomical airway abnormality and should be referred to a specialist for evaluation of the airway anatomy (7).

Other etiologies to consider in a child with fever and stridor include bacterial tracheitis and peritonsillar or retropharyngeal abscesses (RPAs). Patients with bacterial tracheitis typically have initial symptoms suggestive of croup but with progressive development of high fever, toxicity, and purulent tracheal secretions, resulting in airway compromise (8). Peritonsillar abscesses are most common in older adolescents and young adults (9). There is sudden elevation of temperature, ill appearance, and unilateral throat pain following a preceding tonsillitis. The patient complains of trismus, drooling, and a muffled voice (10). Examination may reveal bilateral tonsillar hypertrophy or unilateral tonsillar enlargement with uvular deviation contralaterally (11). Unlike peritonsillar abscesses, RPAs usually present in young children, from infancy to 3 years of age (12). The clinical picture may be similar to epiglottitis but with a less sudden onset (12). Children with RPA present with limitation of neck movement, especially when looking upward. Patients with RPA rarely present with respiratory distress or stridor but do tend to be febrile and ill-appearing. Computed tomography (CT) scan is useful to distinguish

RPA from retropharyngeal cellulitis. Most patients with retropharyngeal cellulitis and a few with RPA can be treated without surgery.

Not infrequently, a URI alone can cause signs of mild-to-moderate respiratory distress in the very young infant. Suctioning the nares with a bulb syringe after placing a few drops of saline can be very useful and may be all that is required in these patients. This is an opportune moment to educate parents on proper suctioning technique so as to optimize home care after discharge from the ED.

Infectious etiologies of the lower respiratory tract that may cause respiratory distress include bronchiolitis and pneumonia. Bronchiolitis presents as any wheezing-associated illness in the first year of life that is preceded by a URI (13). Differentiation from acute attacks of asthma, often triggered by viral infections, may be difficult. As a general rule, patients presenting with wheezing in the first year of life are assumed to have bronchiolitis and not asthma, which therefore precludes treatment with steroids.

In patients presenting in respiratory distress that is not clearly associated with infection, the history and physical examination should quickly provide an answer. Most commonly, a diagnosis of reactive airway disease will be made. An important etiology to include in the differential diagnosis is anaphylaxis, a multisystem syndrome involving the cutaneous, respiratory, cardiovascular, and gastrointestinal systems; involvement of at least two systems is required to make the diagnosis (8). Both the upper and lower airways can be involved, leading to hoarseness, stridor, wheezing, and cough. Early diagnosis and differentiation of anaphylaxis from more benign conditions is essential, as these patients can progress rapidly to anaphylactic shock (8).

Foreign-body aspiration (FBA) can be difficult to diagnose and is a leading cause of death in children under the age of four. Commonly aspirated food products include nuts, seeds, grapes, corn, and beans; peanuts account for nearly 25% of food-based aspirations. Aspiration of hot dogs, candy, and grapes causes the highest mortality. Marbles, coins, toys, and pills are also responsible for many cases (14). The presenting signs and symptoms depend upon

the location of the foreign body in the respiratory tract. A partially obstructing foreign body in the upper airway may cause stridor and shortness of breath and requires immediate intervention to prevent progression to complete obstructions. Children with prolonged cough, unilateral wheezing, or recurrent pneumonias should also be evaluated for FBA. Stridor or wheezing that is not responsive to therapy requires further evaluation, beginning with lateral and anteroposterior radiographs of the neck and chest, preferably during both inspiration and expiration (15).

Not all shortness of breath has an airway, lung, or respiratory cause. Children with myocarditis or cardiomyopathy may present with wheezing and dyspnea. Unfortunately, these entities may easily be confused with RSV, bronchiolitis, bronchitis, or pneumonia. Arrhythmias such as SVT are also common, and may lead to dyspnea and heart failure. Other important causes of respiratory compromise in the child include seizures, cystic fibrosis, and metabolic acidosis caused by sepsis, DKA, renal disease, and certain ingestions (e.g., salicylate, methanol, ethylene glycol).

Neuromuscular diseases, including Guillain–Barré, botulism, and myasthenia gravis, also should be considered. Vocal cord dysfunction, believed to represent a conversion disorder, results in either inspiratory or expiratory stridor that may be confused with wheezing. Congenital anomalies should be considered in infants younger than 6 months who present with stridor; such anomalies include vascular rings, laryngeal webs, vocal cord paralysis, and laryngomalacia. Hypocalcemia, in addition to having neurologic, cardiovascular, and psychiatric manifestations, can also result in apnea, laryngeal spasm, bronchospasm, or biphasic respiratory noises and should be included in the differential diagnosis of any patient with respiratory distress (16).

ED EVALUATION

The pediatric assessment triangle (PAT), comprised of work of breathing, general appearance, and circulatory status, is a widely used evaluation tool for the assessment of the pediatric patient. It is

simple and allows for a rapid global assessment of the potentially ill child. The initial evaluation begins when the physician enters the room, noting any visual and audible indicators of actual or possible respiratory compromise. The child in respiratory distress must be approached in a gentle, reassuring manner and allowed to find the most comfortable position, whether it be on the examining table or on a parent's lap. Initial priorities (concurrent with the PAT triangle) include assessing the relationship between work of breathing and hydration status. Clinicians must establish baselines in these two areas from which clinical changes can be measured. Patients with increased work of breathing, especially infants, are likely to have had greater difficulties feeding and greater insensible water losses from exhaled water vapor. Bringing these two factors together in pediatric patients is vital and goes beyond merely quantifying the respiratory rate. The hydration status is a foundational component of disposition decisions in young infants and children with respiratory illnesses and should not be overlooked. Patients with moderate degrees of tachypnea who otherwise look well must prove that they can maintain their hydration status as outpatients before being discharged.

In the child who is alert and attentive, the evaluation can proceed with the history and physical examination. However, any child with altered mental status, irritability, or restless with other evidence of distress must have an immediate assessment of the ABCs of resuscitation – airway, breathing, and circulatory status.

Important historic points include underlying medical problems (e.g., asthma, cystic fibrosis, or seizure disorder), the onset and type of current symptoms, and the possibility of FBA or ingestion. If epiglottitis is suspected, forced visualization of the pharynx should be avoided in the ED. Forced visualization may result in a vasovagal response, causing cardiopulmonary collapse, respiratory obstruction, and death (17). We recommend the traditional approach where the child with suspected epiglottitis goes to the operating room for direct visualization of the airway under optimal conditions and in the presence of personnel skilled in establishing the airway.

Following the history and physical examination, the etiology of the respiratory distress is usually clear. Noninvasive monitoring can be used to help with clinical assessment. Pulse oximetry provides a continuous and generally valid measure of the arterial hemoglobin oxygenation saturation and arterial pulse. Blood gas measurements stress an already distressed child, add little or no useful information to the evaluation, and should be avoided.

In situations in which FBA is suspected, lateral and anteroposterior neck and/or chest radiographs should be obtained; if normal, either an assisted expiratory film, bilateral decubitus radiographs, or fluoroscopy should be done (18). One should have a low threshold for specialty consultation despite negative imaging results, if FBA is seriously suspected. Direct visualization with bronchoscopy is the test of choice when clinical suspicion is high but the initial evaluation is negative. If the distinction between croup and epiglottitis is not obvious, and the child is stable and only mildly ill, a lateral neck radiograph has been traditionally viewed as appropriate. However, Ragosta et al. (19) found lateral neck films to be of limited value in the initial evaluation of suspected epiglottitis and recommend against their use.

Repeated evaluations at regular intervals, as well as noninvasive monitoring, are essential in any child presenting in respiratory distress. Once appropriate therapy is instituted, the child's response to treatment must be periodically assessed. Often, the best way to determine whether an adult or older child is improving is simply to ask, "Are you feeling better?" In the nonverbal or frightened child, changes in clinical parameters that have been observed early in the evaluation (e.g., activity level, eye contact, and ability to take fluids) are appropriate to gauge improvement.

The plain chest X-ray (CXR) remains the diagnostic tool of choice for the evaluation of dyspnea in pediatric patients. The CXR may reveal pneumothorax, pneumonia, foreign body, pleural effusion, or cardiomegaly, and offers the advantage of being fast and readily accessible.

Ultrasound may gain favor as a diagnostic tool for assessing pulmonary pathology. Ultrasound can be fast and informative,

minimizes radiation exposure, and can be performed at the bedside. Ultrasound also offers the opportunity to repeat examinations serially to monitor for progression of illness or response to treatment. For the diagnosis of pneumonia, ultrasound has been compared to conventional chest radiography and has been judged to be as reliable as CXR in experienced hands (20). However, the use of ultrasound for this indication is still somewhat preliminary; and as with all ultrasound studies the utility of the test is operator dependent.

KEY TESTING

- Pulse oximetry
- Chest radiographs as indicated depending on differential diagnosis
- Thorough history and physical examination

ED MANAGEMENT

The importance of a gentle, nonthreatening approach cannot be overemphasized. Interventions of any sort are usually poorly tolerated by young children and, at least temporarily, may result in a worsening of their condition. The benefit of any intervention must always be weighed against its potential for adversely affecting the child.

Management of the child in respiratory distress generally involves two goals: Keeping the patient calm and comfortable and providing appropriate therapy. Treatment typically begins with humidified oxygen. Infants and some children often do not tolerate masks well and, depending on their oxygen requirement, may best be served with blow-by oxygen administered by the parent. In addition to the physical examination, pulse oximetry is useful in determining oxygenation status. Normal pulse oximetry readings have been reported as 91.5% to 100% in infants 6 months and younger who are awake, and 96% to 100% (median, 99.5%) in children 2 to 16 years of age who are asleep. If the anxiety produced by the administration of oxygen to children in mild distress worsens their

condition, the oxygen is clearly doing more harm than good and should be avoided. However, the anxiety elicited by the administration of oxygen is usually transient. For severely distressed or cyanotic patients, 100% humidified oxygen must be provided quickly, irrespective of their acceptance.

Common diagnoses that respond to specific medical therapy include croup, asthma, and bronchiolitis. Steroids, given orally, parenterally, or via nebulizer, have been shown to be effective in the management of croup, however (10,21–23). For severe croup, nebulized epinephrine can rapidly relieve distress, but its effect lasts only 1 to 3 hours (24). Although nebulized epinephrine's activity is short lived, studies indicate that when it is used with steroids (e.g., dexamethasone, 0.15 to 0.6 mg/kg, intramuscularly or orally), patients can be safely discharged home after 2 to 4 hours if clinically well (e.g., without retractions and stridor at rest) (24–26). Caution should be used when employing nebulized epinephrine if epiglottitis is suspected, as it may precipitate airway obstruction.

CRITICAL INTERVENTIONS

- Keep patients in their position of comfort for as long as possible.
- Consider a foreign body in the patient who presents with paroxysmal cough or new-onset wheezing.
- Give steroids when administering epinephrine for croup.
- Assessing hydration status in conjunction with respiratory status.

DISPOSITION

For the stable child in moderate distress, admission to an inpatient pediatric floor is appropriate. When there is a concern that the patient may deteriorate because of the particular disease process (e.g., anaphylaxis) or medical history (e.g., an asthmatic previously requiring intubation), admission to a PICU should be considered. If necessary, transfer to the nearest hospital having a PICU should be arranged, in accordance with federal guidelines. The transfer should be done by personnel skilled in airway management (i.e., an advanced cardiac life-support unit or the pediatric transfer team of

the receiving hospital). Ground transport is adequate for the stable child in only moderate distress.

Children in severe distress should be admitted to a PICU. If transfer is necessary, consideration should be given to intubating and stabilizing the airway before departure, rather than risking deterioration and the need for a potentially difficult intubation en route. Transfer by ground units with personnel skilled in airway management is adequate for most patients in severe distress. However, the need for ground versus air transport must always be individualized.

Common Pitfalls

- Starting an intravenous line that is not needed for initial therapy (24).
- Forcing oxygen on the child in mild distress who will not tolerate it.
- Obtaining blood for blood gas analysis in a severely distressed patient before providing therapy.
- Doing a detailed history and physical examination before intervening in the severely distressed child.
- Misinterpreting decompensation for improvement.
- During pulse oximetry monitoring, determining a sleeping infant to be hypoxic without further evaluating him or her in an awake state.
- Failing to consider the addition of intravenous fluid therapy in a child with increased insensible losses and decreased oral intake due to tachypnea.

CHAPTER 233

Apnea and Apparent Life-Threatening Events

Raymond Pitetti

An apparent life-threatening event (ALTE) is an incident in a child younger than 2 years characterized by some combination of apnea, color change, abnormal muscle tone, and choking that is frightening to an observer. If a cause for the episode is identified, the course of management is clear. However, most ALTE cases presenting to the emergency department (ED) offer no clues regarding cause. In addition, there are conflicting recommendations regarding how to evaluate and manage children presenting with a first-time ALTE. In 1987, the Consensus Statement of the National Institutes of Health Consensus Development Conference on Infantile Apnea and Home Monitoring was published in an effort to serve as a guide for future research (1). The definitions published in the consensus statement are used in this chapter (Table 233.1). This chapter focuses on the evaluation, differential diagnosis, and management of the neonate and young infant with apnea or an ALTE.

TABLE 233.1
Definitions of Apnea

Apnea: Cessation of respiratory airflow. The respiratory pause may be central or diaphragmatic (i.e., no respiratory effort), obstructive (usually due to upper airway obstruction), or mixed. Short (<15 sec) central apnea can be normal at all ages.

Pathologic apnea: A respiratory pause is abnormal if it is prolonged (>20 sec) or associated with cyanosis, abrupt, marked pallor or hypotonia, or bradycardia.

Periodic breathing: A breathing pattern in which there are three or more respiratory pauses of >3-sec duration with <20 sec of respiration between pauses. Periodic breathing can be normal.

Apnea of prematurity: Periodic breathing with pathologic apnea in a premature infant. Apnea of prematurity usually ceases by 37 wks' gestation (menstrual dating) but occasionally persists for several weeks past term.

Apparent life-threatening event: An episode that is frightening to the observer and that is characterized by some combination of apnea (central or occasionally obstructive), color change (usually cyanotic or pallid but occasionally erythematous or plethoric), marked change in muscle tone (usually marked limpness), choking, or gagging. In some cases, the observer fears the infant has died.

Apnea of infancy: An unexplained episode of cessation of breathing for 20 sec or longer, or a shorter respiratory pause associated with bradycardia, cyanosis, pallor, or marked hypotonia. The term *apnea of infancy* generally refers to infants who are more than 37 wks' gestational age at onset of pathologic apnea. Apnea of infancy should be reserved for those infants for whom no specific cause of an ALTE can be identified. In other words, these are infants whose events are considered idiopathic and believed to be related to apnea.

Reproduced with permission from the National Institutes of Health Consensus Development Conference on Infantile Apnea and Home Monitoring. Consensus statement. *Pediatrics*. 1987;79:293.

Apnea, one of many types of breathing problems seen predominantly in infants and is defined as the cessation of breathing for 20 seconds or longer, or for a shorter period when accompanied with bradycardia, cyanosis, pallor, or hypotonia. Apnea may or may not occur in an infant who has had an ALTE.

The incidence of ALTE in infants is reported to be between 0.5% and 6% of all children, and mortality rates to range from 2% to 6% (2). Infants presenting with apnea during sleep may have a mortality of up to 10%, with the risk of death tripling with two or more recurrences. In more than 50% of ALTEs, no definitive cause can be found (2).

ALTE should be differentiated from sudden infant death syndrome (SIDS). SIDS occurs in about 2 per 1,000 live births in the United States and has been defined as "the sudden death of an infant less

than 1 year of age that remains unexplained after a thorough case investigation, including performance of a complete autopsy, examination of the death scene and review of clinical history" (3). The National Institute of Child Health and Development Cooperative Epidemiological Study of SIDS found that only 2% to 4% of cases had a hospital record of apnea of prematurity and only <7% had a history of an acute life-threatening event (1). Therefore, ALTEs, though historically termed "near SIDS," are not thought to be a precursor or risk factor for SIDS. The American Academy of Pediatrics has made several new recommendations regarding SIDS prevention; these are listed in Table 233.2.

TABLE 233.2
AAP Recommendations on SIDS Prevention

Neonate/Infant	Both	Toddler/Young Child
Stridor		
Vascular ring	Vocal cord paralysis	
	Foreign body

	Laryngomalacia	Tracheostomy plug
	Tracheomalacia	Subglottic stenosis
		Bronchopulmonary dysplasia
Abnormal Airway		
Choanal atresia/ stenosis	Craniofacial abnormalities	Large tonsils/adenoids
Tracheoesophageal fistula		
Other	Gastroesophageal reflux	
	Hemangioma/ lymphangioma	
	Pharyngeal/retro-pharyngeal mass	

CLINICAL PRESENTATION

In the neonate and young infant, apnea is the final common pathway of many pathophysiologic processes. Respiratory function is a complex system that is regulated in the pons and medulla, which receive afferent stimuli from chemoreceptors, as well as stretch receptors in the bronchioalveolar tree. Efferent impulses from respiratory centers are mainly found in the vagus, phrenic, and intercostal nerves. The neonate has a greater concentration of nerve endings and smooth muscle in and around the walls of the smaller airways and a thinner pulmonary arterial wall that contributes to decreased vascular resistance.

These features, coupled with the overall immaturity of the cardiorespiratory system, translate into wide swings in both pulmonary vascular and distal airway resistance, resulting in acute ventilatory-perfusion disturbances, intrapulmonary shunting, and hypoxemia. In addition, gastroesophageal reflux has been associated with central, obstructive, or mixed apnea secondary to reflex hypoxemic episodes.

There is no typical clinical setting or presentation of a child with apnea. Most children are brought to the ED in stable condition by the parents, who say the child "stopped breathing." The child may present, however, in cardiopulmonary arrest or in respiratory distress with an unstable airway (see Chapter 217 for management). Infants who present with an ALTE may or may not have had a reported episode of apnea.

It is vital to determine the child's position and activity, and the exact sequence of events before and during an episode of apnea or ALTE (4). The child may have spontaneous inspiratory effort or may require stimulation after an apneic episode. The child may also be noted to have a change in color, usually cyanosis, but the color may vary from pallid to erythematous. Changes in muscle tone can be seen before or during the apneic event. Changes in tone may vary from arching or extension of the extremities to marked hypotonia and limpness (5). An understanding of the specific event sequence may help guide the diagnosis; for instance, arching with apnea after feeding, with or without formula in the oronasal passages, can be attributed to gastroesophageal reflux (6).

In general, there are two types of apnea: (1) obstructive and (2) central. An absence of respiratory airflow in the presence of respiratory effort and chest wall movement suggests obstructive apnea. The absence of all three elements—respiratory effort, chest wall movement, and respiratory airflow—is consistent with central apnea.

Parents are usually extremely frightened by what they have seen and frequently believe their child is dying. In most cases, parents administer some form of cardiopulmonary resuscitation (CPR) or stimulation. A thorough history is vital to determine whether CPR was actually necessary.

DIFFERENTIAL DIAGNOSIS

The differential diagnoses of apnea and ALTE in neonates, infants, and older children are shown in **Tables 233.3** to **233.5** (7). Davies and Gupta (8) found the most common discharge diagnoses in patients admitted with an ALTE to be gastroesophageal reflux (26%) (9), seizures (9%), pertussis (9%), and urinary tract infection (5%). Apnea may be the only manifestation of a seizure, or a seizure may be precipitated by a hypoxic event. In the toddler and young child, foreign body ingestion and poisoning should also be considered.

TABLE 233.3
Differential Diagnosis of Obstructive Apnea

Neonate/Infant	Both	Toddler/Young Child
Stridor		
Vascular ring	Vocal cord paralysis

	Neuromuscular disorders
	Munchausen syndrome by proxy
	Metabolic disorders

Often, the clinician must differentiate between a breath-holding spell and an ALTE. A breath-holding spell is an involuntary event occurring during expiration while a healthy toddler or young child is awake (10). The most common type is the cyanotic or classic spell, which begins with crying, usually after an obvious precipitating event. The child then stops breathing at end expiration, which results in cyanosis and loss of consciousness. The spell usually resolves spontaneously, with resumption of breathing and the patient's gradual recovery to a baseline state. There may be associated body jerks and urinary incontinence (6). This sequence and description of a breath-holding spell does not apply to spells occurring during sleep. A cyanotic spell differs from a pallid breath-holding spell which involves a sudden painful incident, with resulting vagally mediated bradycardia or asystole. The patient turns pale and limp and may have tonic–clonic seizure activity, but ultimately resumes normal behavior.

Child abuse has been detected in 2.3% of patients presenting with an ALTE and, therefore, should be considered in all infants

presenting in this manner (11,12). Infants should be examined for retinal hemorrhages or signs of increased intracranial pressure. Patients suffering from Munchausen syndrome by proxy (MSBP) may present with recurrent episodes of apnea or cyanosis as a consequence of repeated intentional suffocation by a parent or caregiver. Apnea is the chief presenting complaint in about 20% of cases of MSBP (13).

Cyanotic congenital heart disease usually presents in the first few weeks of life and is due to varying degrees of right-to-left shunt; lower pulmonary blood flow (due to greater degrees of shunting) results in more severe cyanosis. These children tend to have feeding difficulties and poor weight gain. The administration of 100% oxygen can differentiate pulmonary from cardiac causes of cyanosis. The oxygen saturation measurement and PaO_2 increase when cyanosis is secondary to a pulmonary cause and typically fail to increase in an infant with cyanotic congenital heart disease.

Infants with *Bordetella pertussis* typically do not present with the classic history of a "whooping" cough. However, they can present with apnea, prolonged coughing, and post-tussive episodes of vomiting. Similarly, infants early in the course of respiratory syncytial virus (RSV) infection may present solely with apnea and no other symptoms. Many infants who are on home monitors because of a history of apnea are brought to the ED for "frequent alarms." False alarms account for more than 90% of monitor alarm events (14) and typically are due to shallow breathing or loose lead placement (5). A thorough history usually helps to differentiate between a true apneic event and a false alarm.

ED EVALUATION AND MANAGEMENT

Most infants who present to the ED with a history of an ALTE appear well and have a normal physical examination. However, a complete and thorough history and physical examination should nonetheless be performed.

A detailed history can help to determine an underlying cause of an event or determine which patients are at a higher risk for subsequent morbidity and mortality. The following information is helpful in risk-

stratification and determining the likelihood of a serious underlying disorder.

The Event

- Who was present during the event?
- Was there any preceding history?
- How was the caretaker alerted to the event?
- How was the infant found, including position of the baby?
- Was there vomitus or blood in the mouth or nose?
- Was the baby's color different (e.g., blue, red, pale) from normal?
- What was the baby's tone like?
- What was the baby's conscious state like?
- Was the baby moving?
- Was the baby breathing?
- What did the caretakers do?
  - Did they perform back blows?
  - Did they perform mouth-to-mouth breathing and chest compressions?
- How long did it take for the baby to recover?

It is important to remember that apnea lasting less than 15 seconds is likely to be benign in nature and does not require further medical evaluation or treatment. However, any period of apnea that is associated with a color change should be taken seriously. When talking with caregivers about color changes, ask exactly what color the baby was, where the color change occurred on the child's body, the duration of color change, and the room lighting. As a general rule, cyanotic changes are of more concern than episodes in which the infant was noted to "turn red." Perioral cyanosis is evidence of central hypoxia and must be further evaluated.

One historical element that helps to distinguish an ALTE due to organic disease from one due to nonaccidental trauma (NAT) is inconsistently explained ALTEs witnessed by the same caregiver. This pattern is of particular concern if the events decrease in frequency or cease upon admission to the hospital or if the events suffered in the hospital occur only in the presence of the same caregiver. When

initially interviewing the caregiver of an ALTE patient with suspected NAT, it should be assumed that the observer's account is accurate and reliable, even if the events do not seem credible at the time.

Past medical history: This should include that of the baby's birth, feeding practices, growth history, immunization status, developmental history, and history of previous similar episodes. In addition, a recent history of illness and medication use should also be obtained. Caregivers should be questioned as to use of prescription medications, over-the-counter medications, and homeopathic or herbal remedies. Breastfeeding mothers should be asked what medications, both prescribed and otherwise, they are taking that could be transmitted to the infant via breast milk.

Family history: Caregivers should be questioned about a family history of ALTE, SIDS, congenital heart disease, epilepsy, or other unusual illnesses that may present in young children. Interestingly, a family history of SIDS may be found in as many as 15% of patients presenting with an ALTE (8).

Social history: A detailed social history may identify social and environmental precipitants of the event. In particular, the presence of smokers in the home, the type of heating in the dwelling (risk of carbon monoxide poisoning), and factors that may indicate possible child abuse may help guide the clinical decision-making and disposition decisions.

Children who present with an ALTE should have a complete physical examination, including a thorough neurologic examination and developmental assessment. In addition, a dilated fundoscopic examination should be performed, if possible. However, it is likely that the child's examination will be normal. Specific physical examination findings that may help in identifying the underlying cause of the events could include the presence of retinal hemorrhages (child abuse), unusual bruising (child abuse), neurocutaneous findings (tuberous sclerosis), or a full anterior fontanelle (increased intracranial pressure). The oropharynx must be carefully examined for evidence of abnormal bruising beneath the tongue, the gums, and on the inner aspect of the buccal mucosa or

the frenulum. Such evidence may be indicative of a smothering attempt.

After the history and physical examination, the physician should be able to conclude whether the child has had an ALTE and whether any apneic event was obstructive, central, or mixed (see **Tables 233.3–233.5**). If there was a significant event consistent with ALTE, a consultant should be contacted for further inpatient evaluation and management (Fig. 233.1).

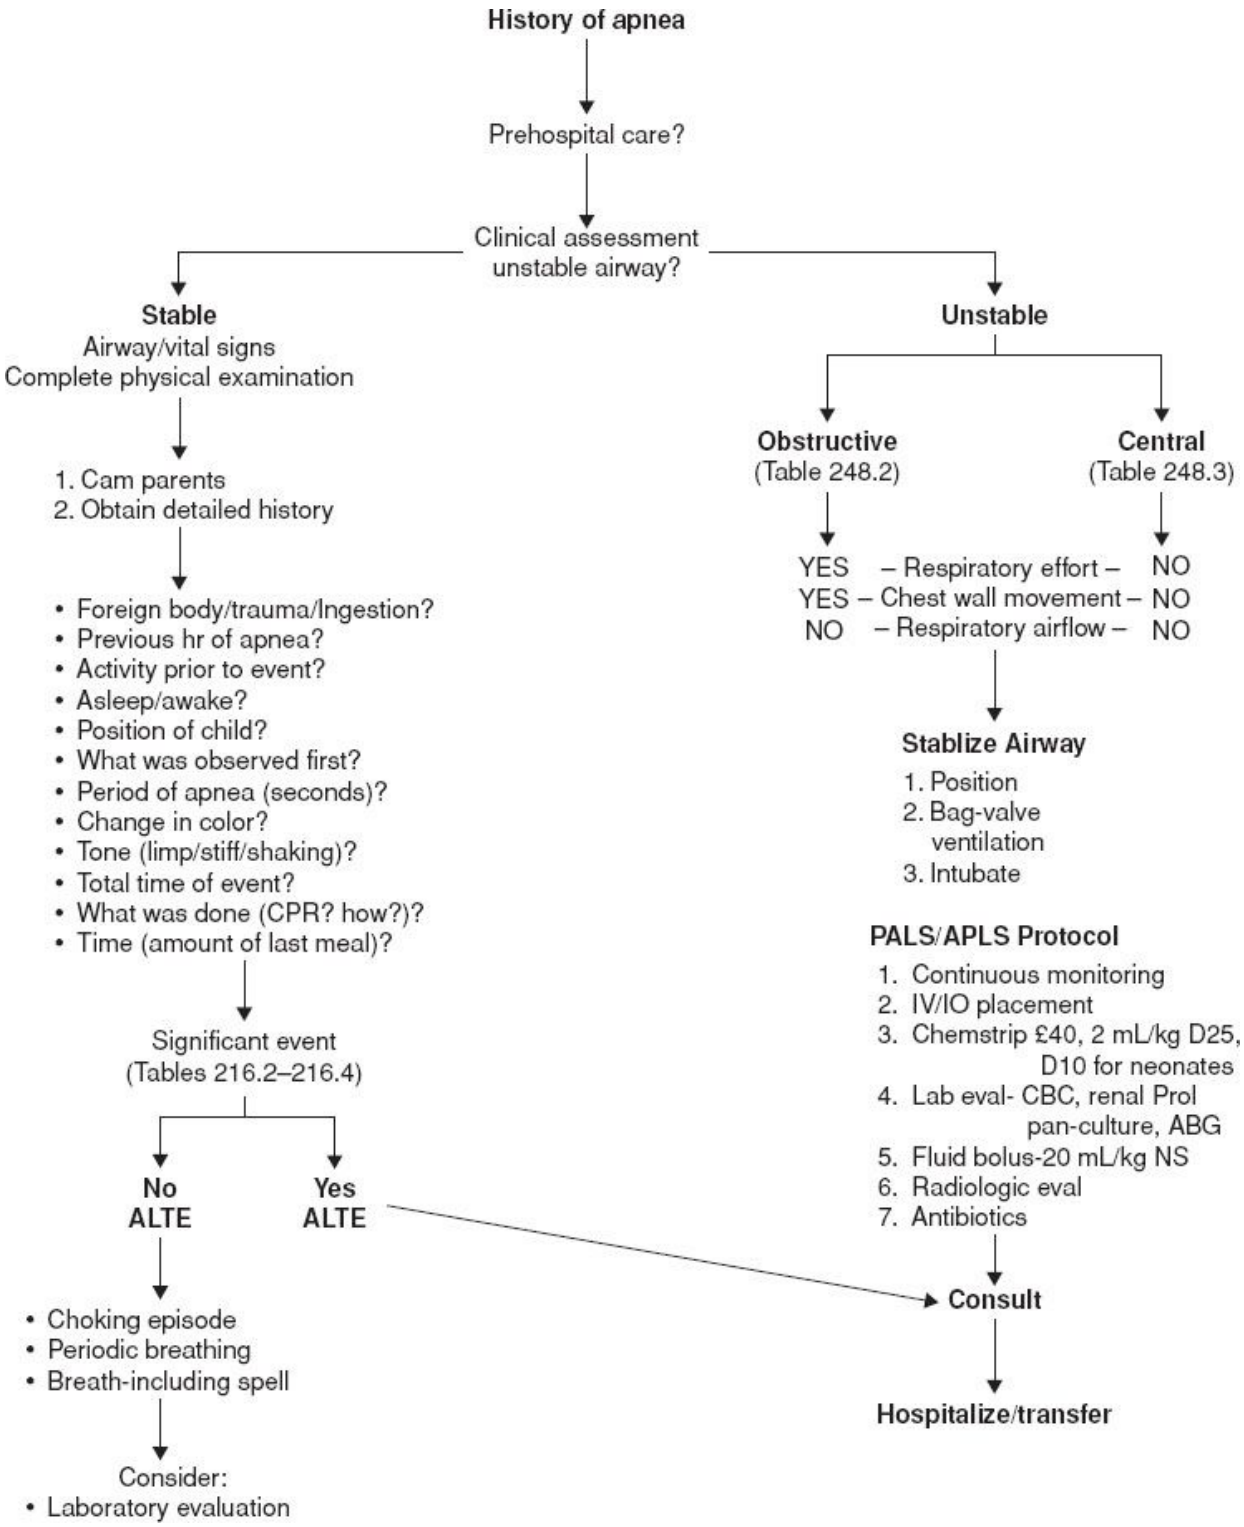

FIGURE 233.1 Algorithm for ED management and evaluation of apnea in an infant/young child.

Laboratory evaluation must be guided by the history and physical examination and may include a complete blood count, renal profile, urinalysis, blood and urine cultures, and possibly pertussis, chlamydia, and RSV studies. RSV testing should be performed in infants who were premature and in those with congenital heart disease; as noted above, infection with RSV is associated with an increased risk of apnea (14).

The radiographic evaluation consists of a chest radiograph and, if upper airway obstruction is suspected, anteroposterior and lateral soft-tissue radiographs of the neck. Occasionally, patients with apnea have ingested caffeine or aminophylline; therefore, a theophylline level may be checked (4).

An electrocardiogram may be obtained to rule out arrhythmias; supraventricular tachycardia, ventricular tachycardia, and prolonged QT syndrome, in particular. In addition, a computed tomography scan of the head or cranial ultrasound may be obtained in patients with an altered level of consciousness, abnormal muscle tone, focal neurologic findings, or retinal hemorrhages. Further inpatient evaluation may include an EEG, swallowing studies, esophageal pH probe, and polysomnography (2).

Diagnostic evaluations must be tailored to the history and physical examination findings. While some patients may require extensive evaluations, many others may not mandate such extensive testing. An ECG, chest x-ray, urinanalysis, and finger-stick glucose may help to rule out a number of important causes of ALTE.

One systematic review pertaining to ALTEs sought to determine what historical and physical examination findings placed an infant at risk for a future adverse event or serious underlying diagnosis and to determine what testing is indicated (15). A history of prematurity, multiple ALTEs, or suspected child maltreatment were identified as significant risk factors. It was also concluded that routine screening tests were of low yield in infants without historical risk factors or suggestive physical examination findings.

A recent study by Willwerth et al. reported factors that were associated with an increased risk of apnea. These included (1) full-term infants younger than 1 month; (2) premature infants younger

than 48 weeks postconception age; and (3) infants with witnessed apneic episodes prior to presentation to a physician (16). Another smaller study evaluated 59 infants with ALTE and recommended outpatient management for infants older than 1 month with only one episode of apnea (17). This was a relatively small study, however, and it is thus still prudent to admit all patients with ALTE until larger studies can confirm these recommendations.

CRITICAL INTERVENTIONS

- Obtain bedside glucose.
- Check electrocardiogram for dysrhythmias and prolonged QT syndrome.
- Consider a full septic workup, especially in infants younger than 2 months.
- Consider pertussis and RSV studies.
- Perform neuroimaging in patients with altered mental status or abnormal neurologic findings.

DISPOSITION

Any child who meets criteria for an ALTE, should be admitted for further evaluation, observation, and parental education, despite a normal initial evaluation. Most children can be admitted to a general pediatric ward with an apnea-bradycardia monitor to detect apneic episodes and to determine their frequency and duration and any associated bradydysrhythmias.

Common Pitfalls

- Failing to believe the caretaker about the event, particularly when the child is happy and alert on presentation.
- Failing to obtain an immediate bedside glucose level. It should be repeated within 5 minutes after giving the dextrose bolus. Sepsis can present with respiratory instability, and hypoglycemia must be treated.
- Failing to hospitalize patients with ALTEs.

CHAPTER 234

Chest Pain and Palpitations

Steven M. Selbst

CLINICAL PRESENTATION

Children frequently present to the emergency department (ED) with the complaint of chest pain. While not as common as abdominal pain or headache, chest pain is a frequent complaint in children. Between 0.3% and 0.6% of visits to a pediatric ED are for chest pain (1,2). The symptom occurs equally in boys and girls, and it is found in children of all ages and races. Approximately one-third of children with this complaint are awakened from sleep by the pain, and one-third miss school because of the pain (2). The mean age of children with this complaint is about 12 years (2).

Unlike adults, children with chest pain *rarely* have serious organic pathology (2–7). Most children with chest pain are not in extremis and the pain is not acute in nature. Understandably, patients and their families associate chest pain with heart disease, and are frightened by media reports of sudden death in young athletes. Infrequently, pediatric chest pain will present with significant distress and require immediate resuscitation in the ED, and while, regardless of the presentation, the complaint should be taken seriously, *fatal heart disease is extremely rare in the pediatric population.* In general, a thorough history and careful physical examination can guide the emergency physician to order appropriate laboratory studies and to refer a child with chest pain to a specialist for further evaluation, if indicated (1,2,7).

DIFFERENTIAL DIAGNOSIS

Age is a helpful tool for stratifying potential etiologies of pediatric chest pain. Young children are more likely to have a cardiorespiratory cause for their pain, such as cough, asthma, pneumonia, or cardiac pathology (including myocarditis, pericarditis, arrhythmia, or ischemia), while adolescents are more likely to have pain associated with stress or a psychogenic disturbance (1,2). Because there are occasional children with serious pathology related to chest pain, the ED physician must carefully contemplate an extensive differential diagnosis when evaluating a child with chest pain (see **Tables 234.1** and **234.2**).

Idiopathic

Cardiac Pathology

Previously undiagnosed cardiac pathology is a rare cause of chest pain in children but should be considered. A recent study showed that <1% of children with chest pain presenting to a pediatric ED had previously unrecognized heart disease as the etiology for their pain (4). Myocardial ischemia or infarction should be considered in any child who has pain with exertion or syncope (8,9). Myocardial infarction (MI), particularly in young infants, can result from an anomalous coronary artery, often with no warning of this underlying condition. Some children, however, will have a pansystolic, continuous, mitral regurgitation murmur or gallop

rhythm suggesting myocardial dysfunction. In many cases, exercise (e.g., feeding for infants) induces chest pain secondary to increased myocardial oxygen demand in the face of limited coronary blood flow. Electrocardiograms (ECGs) in these patients may demonstrate a classic ST elevation MI pattern typically seen in adult patients.

Some children may have medical and social histories that predispose them to a higher likelihood of angina or infarction. For instance, children with long-standing diabetes mellitus may develop coronary artery disease leading to angina or MI. Patients with a past history of Kawasaki disease may have coronary artery aneurysms, which may produce problems long after the original illness (10). Pediatric patients with chronic anemia, such as sickle cell disease, are also at risk for angina or other cardiac pathology as are teenagers who abuse cocaine. Cocaine causes tachycardia and vasoconstriction, which can lead to increased oxygen demand, hypertension, and chest pain (4,11). Arrhythmias can cause palpitations, pain, or an abnormal cardiac examination. Supraventricular tachycardia is the most common of these arrhythmias in childhood, but premature ventricular tachycardia can also lead to episodes of brief, sharp chest pain (4,12).

Some children with structural abnormalities of the heart may develop ischemia and chest pain. One structural abnormality deserving special mention is hypertrophic obstructive cardiomyopathy, which is the leading cause of sudden cardiac death in children and adolescents. This disorder has an autosomal dominant pattern of inheritance, so there is often a family history. Children with this disorder have a murmur best heard when the patient is standing or performing a Valsalva maneuver. The ECG may reveal left ventricular hypertrophy, ST segment depression, and T-wave inversion. The risk for ischemic chest pain increases with exertion (7–9,13).

Cardiac infections such as pericarditis and myocarditis, although uncommon, should be considered as potential causes of pediatric chest pain (4,13). Children with pericarditis may present with sharp, stabbing, midsternal chest pain that improves when the patient sits up and leans forward. The child with this infection is usually febrile

and may be in respiratory distress. A friction rub is pathognomonic for pericarditis but is present in only 25% of cases (14). Distant heart sounds are more likely with a large accompanying pericardial effusion; neck vein distention and *pulsus paradoxus* suggest pericardial tamponade (13). Myocarditis is more common and may present more subtly (15–17). The condition is often misdiagnosed because the signs and symptoms mimic other conditions such as influenza infection. Children with myocarditis have mild, nondisruptive chest pain for several days (13,16,17). After 2 to 4 days of fever and other systemic symptoms such as vomiting and lightheadedness, the patient may develop chest pain with exertion and shortness of breath (15–16). Examination may reveal muffled heart sounds, a low-grade fever, tachypnea, a gallop rhythm, or tachycardia that is out of proportion to the degree of fever present. The patient may also have orthostatic changes in pulse or blood pressure (pulse increase >30 beats/min, blood pressure decrease by >20 mm Hg when moving from supine to standing position). These changes are often misinterpreted as volume depletion because children with myocarditis may not drink well and may indeed be mildly dehydrated. However, cardiogenic causes such as myocarditis should be suspected when orthostatic changes do not improve with fluid resuscitation. In both myocarditis and pericarditis, a chest x-ray usually shows cardiomegaly and the ECG is abnormal, prompting further evaluation with an echocardiogram (13,16,17).

Musculoskeletal Pain

Musculoskeletal pain is one of the most common diagnoses in children with chest discomfort (2,4,18). Active children frequently strain chest wall muscles while wrestling, carrying heavy books, or exercising. Some children suffer a mild contusion of the chest wall from direct trauma. With more significant force, a rib fracture, hemothorax, or pneumothorax is possible. In most cases, there is a straightforward history of trauma and the diagnosis is clear. Generally, a careful physical examination will reveal chest wall

tenderness, bruising or pain with movement of the torso or upper extremities.

Costochondritis is a related musculoskeletal disorder that is common in children. This disorder is characterized by mild to moderate anterior chest wall pain that may radiate to the chest, back, or abdomen. Exercise or an upper respiratory infection may precede the pain. The pain may be bilateral, and is generally sharp and exaggerated by physical activity or breathing. Eliciting tenderness over the costochondral junctions with palpation makes the diagnosis. Such pain may persist for several months (7,18).

Respiratory Conditions

Many children have a respiratory condition as the etiology for their chest pain (2–4). For instance, children with severe, persistent cough or asthma may complain of chest pain caused by overuse of chest wall muscles. Diagnosis is made by history or the findings of rales, wheezes, tachypnea, or decreased breath sounds. Some children who complain of chest pain with exercise may have exercise-induced asthma, a diagnosis readily established by a treadmill test (3). In addition, an occasional teenager will develop a spontaneous pneumothorax or pneumomediastinum and complain of pain associated with respiratory distress (19,20). Children at high risk for these conditions are those with asthma, cystic fibrosis, or Marfan syndrome (18,19). However, previously healthy children may rupture an unrecognized subpleural bleb with minimal precipitating factors such as coughing, sneezing, stretching. If the pneumothorax is significant, the patient can have respiratory distress, and possibly decreased breath sounds on the affected side or palpable subcutaneous air (19). Adolescents who snort cocaine are at risk for similar barotrauma and may complain of severe, sudden chest pain with associated anxiety, hypertension, and tachycardia (11,13).

Chest pain associated with fever should prompt concern for an infectious etiology such as pneumonia (1,2,4). Most such patients have a history of cough and may also be tachypneic. In addition,

children with underlying systemic lupus erythematosus may develop a pleural effusion causing chest pain worsened by deep inspiration. Auscultation of decreased breath sounds should raise suspicion for this condition, and radiographs should confirm the presence of an effusion.

Finally, pulmonary embolism is extremely rare in pediatric patients but may be considered in an adolescent girl with dyspnea, fever, pleuritic pain, cough, and hemoptysis. The likelihood of this diagnosis is increased if the patient has a central venous catheter, had recent surgery, had recent trauma, is taking birth control pills, or recently had an abortion (18,21).

Psychogenic Disturbances

Psychogenic disturbances can precipitate chest pain in both boys and girls at equal rates. Stress-related pain accounts for about 10% of children with chest pain who present to the ED (1,2,18). Often the anxiety and stress that results in somatic complaints is not easily apparent. Not all such children present with hyperventilation or an anxious appearance. A careful history is essential. If the child has had a recent major stressful event such as separation from friends, death or divorce in the family, or school failure that correlates temporally with the onset of the chest pain, it is reasonable to suspect that the symptoms are related to underlying stress (7,18).

Gastrointestinal Disorders

Gastrointestinal disorders such as reflux esophagitis often cause chest pain in young children and adolescents. The pain is classically described as burning, substernal, and worsened by reclining or eating spicy foods. The diagnosis can be made clinically or with a therapeutic trial of antacids (7).

Some young children complain of acute chest pain following the ingestion of a coin, button battery, or other foreign body that lodges in the esophagus (18).

Likewise, some adolescent patients may present to the ED with pill-induced esophagitis. Teenagers who take pill medications,

especially tetracycline or doxycycline, can develop esophagitis, particularly when the medication is taken with minimal water and the teen lies down (22). Doxycycline produces an acidic solution or gel as it dissolves, and it is caustic when it remains in the esophagus. Symptoms may be noted several days after beginning the medication, but frequently pain occurs after taking the first dose. A careful history makes the diagnosis; physical examination is likely to be unremarkable (22).

Miscellaneous

Miscellaneous causes of chest pain include pain related to underlying diseases. For instance, a child with sickle cell disease may have a vasoocclusive crisis, which localizes in the chest or produces acute chest syndrome (4). Marfan syndrome may result in chest pain and fatal dissection of an abdominal aortic aneurysm (18). Herpes zoster infection, or shingles, may produce severe chest pain that precedes the classic vesicular rash by several days or occurs simultaneously. Coxsackievirus may rarely lead to pleurodynia with paroxysms of sharp pain in the chest or abdomen ("devil's grip"). Teenagers or preteens may complain of chest pain when there is breast tenderness from physiologic changes of puberty or from early changes of pregnancy. A child with a thoracic tumor (Hodgkin disease or non-Hodgkin lymphoma) may present with chest pain but undoubtedly would have other signs and symptoms of disease as well (7). The pain may also be part of an underlying systemic disorder such as a collagen vascular disease (if there is also joint pain, rash, or fever).

Precordial catch syndrome (Texidor twinge or "stitch in the side") may explain unilateral chest pain that lasts a few seconds or minutes and is associated with bending or a slouched posture. It is believed that this pain arises from the parietal pleura, but the etiology is unclear. Straightening up and taking shallow breaths relieves the pain. The pain may recur often or remain absent for months (23). Finally, some children may complain of pain under the ribs, and sometimes hear a clicking or popping sound when they lift objects,

flex the trunk, or walk; these patients have a rare disorder called "slipping rib syndrome" (24).

Similar to abdominal pain, in 20% to 45% of cases of pediatric chest pain, no diagnosis can be determined with certainty. Therefore, the child's pain is often labeled as idiopathic and it is incumbent upon the emergency physician to have thoughtfully eliminated the most life-threatening entities from the differential diagnosis and provide families with appropriate return instructions or follow-up as needed (7).

DIAGNOSTIC APPROACH

A complete history is vital and reveals the etiology of chest pain in most cases. Family history may also be helpful with disorders such as hypertrophic obstructive cardiomyopathy where previous familial sudden deaths may yield vital clues (8,13). Past medical histories of previous ischemic heart disease or conditions such as asthma, diabetes mellitus (hyperlipidemia), or Kawasaki disease potentially place patients at greater risk for serious causes of their pain (10,18).

Keeping in mind that young children are often vague in their descriptions, it is important to determine the location, onset, frequency, and severity of the pain and most importantly if it interrupts the child's daily activities. Children with acute onset or who are awakened from sleep because of pain are more likely to have an organic etiology, although not necessarily serious disease (1,2). Those with chronic pain who have gone for extended periods without a diagnosis are more likely to have idiopathic or psychogenic pain (2). Burning pain in the sternal area suggests esophagitis, and sharp stabbing pain relieved by sitting up and leaning forward suggests pericarditis in a febrile child (13).

Precipitating factors associated with the pain should also be carefully investigated; a history of trauma, rough play, or choking on a foreign body may be quite relevant. Exertional chest pain should always be taken seriously, as it may be related to either cardiac disease or, more commonly, exercise-induced asthma. Associated complaints such as syncope or palpitations are also

significant and may be indicative of undiagnosed cardiac disease. Chest pain associated with fever makes an infectious process such as pneumonia or myocarditis more concerning.

A careful physical examination, beginning with vital signs as a first priority, will likely point to the cause of the pain. A quick general assessment often differentiates the child in severe distress such as a patient with a pneumothorax, from those with more benign causes of chest pain. This subjective assessment may also yield other subtle clues to the diagnosis. For example hyperventilation may be distinguished from respiratory distress by the absence of cyanosis or nasal flaring. Signs of chronic disease such as pallor or poor growth suggest a more complex problem like a neoplastic process (e.g., mediastinal mass) or collagen vascular disease. Consider the possibility of Marfan syndrome if the patient is tall and thin with an upper extremity span that exceeds his or her height. Examine the skin for rashes or other lesions. Bruises distant from the chest may indicate unrecognized chest trauma. Carefully examine the abdomen for sources of referred pain to the chest. Note any signs of anxiety that could indicate the presence of emotional stress. The origins of psychogenic pain should be carefully evaluated and not be treated as a diagnosis of exclusion; it is imperative to enquire about stressful conditions at home or school (see Chapter 289). For some adolescents with chest pain, substance abuse (cocaine, in particular), use of birth control pills (pulmonary embolism), and oral medications (pill-induced esophagitis) (22) should be considered. Table 234.3 summarizes important history in a child with chest pain.

TABLE 234.3
History Questions for Children with Chest Pain

When did the pain begin?
How severe is the pain?
How often does the pain occur?
How long does the pain last?
What is the pain like?
What seems to bring on the pain?
Are there associated symptoms?
What is the child's past medical history?
Is there a family history of heart disease or chest pain?
What treatments for the pain have been tried?
What is the patient or guardian concerned about?

A complete cardiopulmonary examination may reveal important findings such as rales, wheezes, decreased breath sounds, murmurs, rubs, muffled heart sounds, clicks, or arrhythmias that may indicate the need for an ECG and/or chest x-ray. A murmur that intensifies with Valsalva and the standing position is the hallmark of hypertrophic cardiomyopathy. The chest wall should also be evaluated for external signs of trauma, tenderness (suggesting musculoskeletal pain), or subcutaneous air (suggesting a pneumothorax or pneumomediastinum) (19,20).

Chest radiographs and ECG should not be routinely ordered unless indicated by the history and/or physical examination (18; see Table 234.4). A chest x-ray and/or ECG are more often indicated if the history reveals acute onset of pain (beginning in the prior 2 or 3 days) or is otherwise concerning for pulmonary problems or cardiac pathology (e.g., tachypnea, or tachycardia, or exercise induced) (18). Exertional pain should prompt consideration of cardiac ischemia or asthma, and warrants an ECG and chest x-ray and potentially a referral for exercise stress testing, although the value of this is controversial (1–7,18). Fever with chest pain is highly correlated with pneumonia, but pericarditis or myocarditis should also be considered if cardiomegaly is noted on the chest radiograph.

TABLE 234.4
Indications for Laboratory Studies in Children with Chest Pain

Worrisome History

Acute onset of pain

Pain on exertion

History of heart disease

Serious associated medical problems (diabetes mellitus, asthma, Marfan syndrome, Kawasaki disease, anemia, lupus erythematosus)

Use of drugs (cocaine, oral contraceptives)

Associated complaints (syncope, dizziness, palpitations)

Significant trauma

Foreign body ingestion/aspiration

Fever

Abnormal Physical Examination

Respiratory distress

Palpation of subcutaneous air

Decreased breath sounds

Cardiac findings (murmurs, rubs, arrhythmias)

Fever

Trauma

Laboratory studies usually only confirm previously known disorders or abnormal findings already suspected clinically. If the history and physical examination do not lead to a specific diagnosis for chest pain, laboratory tests are unlikely to be helpful. This is especially true in the child with chronic pain, a normal physical examination, and no history to indicate cardiac or pulmonary disease. Reassure the family the child is unlikely to have a serious etiology for the pain and that studies will not be helpful. Blood counts and sedimentation rates are of limited value unless sickle cell disease, collagen vascular disease, infection, or malignancy are suspected. A drug screen for cocaine may be indicated in the older child with acute pain and associated anxiety, tachycardia, hypertension, or shortness of breath. Cardiac enzymes are rarely of value unless there are specific concerns for ischemic disease from the history or examination.

CRITICAL INTERVENTIONS

- Enquiring about the presence of exertional pain, syncope, or fever.
- Obtaining an ECG and oxygen saturation.
- Ascertaining whether the patient has an underlying disease process such as diabetes, Marfan syndrome, or systemic lupus.
- Enquiring about drug use and obtaining a toxicology screen if necessary.

DISPOSITION

The child in severe distress or with abnormal vital signs should be admitted to the hospital for monitoring, further diagnostic studies, and treatment. Patients who have exertional pain, dizziness, palpitations or syncope should be urgently referred to a cardiologist for further evaluation which may include a Holter monitor or echocardiogram to evaluate for an arrhythmia or structural heart disease (7,8,25). Similarly, a child with known or suspected heart disease may be best served by a visit to a cardiologist even if the pain proves to be unrelated. A specialist should also be consulted for patients with suspected esophageal foreign body for rapid removal of the object. If the patient has a serious emotional problem that cannot be managed by the ED staff, referral to a psychiatrist is warranted.

In all cases, appropriate follow-up should be arranged; many children with ill-defined chest pain have persistent symptoms for many months. Although serious organic pathology is unlikely to be found in the future, some patients are kept from participating in their usual activities because of the pain, and some patients manifest significant psychoemotional problems or exercise-induced asthma that was not recognized at the initial ED visit (26,27).

Common Pitfalls

- Failure to consider serious pathology (e.g., myocarditis) in the child with chest pain.
- Failure to consider pneumonia or viral myocarditis in febrile patients with chest pain.

- Failure to consider cardiac disease if pain is associated with exertion, syncope, or dizziness.
- Failure to consider esophageal foreign body (e.g., coin ingestion) in a toddler with sudden onset of chest pain.

CHAPTER 235
Syncope

Sharon E. Mace

Syncope is the sudden transient loss of consciousness (LOC) accompanied by an inability to maintain postural tone, with spontaneous resolution. The sensation or feeling of being about to pass out is near-syncope or presyncope. The causes and management are analogous to that for syncope. Syncope is a common complaint in patients of all ages, accounting for 1% to 1.5% of emergency department (ED) visits and up to 6% of hospital admissions (1,2). In children and adolescents, syncope accounts for 2% of pediatric ED visits (3) and 5% of pediatric hospital admissions (4,5). In the pediatric population, syncope occurs more often in females than males, and most often in adolescents, with the highest incidence in the 15- to 19-year-old age group (6). About 25% of all adolescents will have had at least one syncopal episode (7), although higher incidences of nearly 50% have been reported (8,9).

The etiology of syncope is established in only about half of adult patients following an initial ED visit and in only 70% of patients who have been admitted to the hospital (10). The findings in pediatric patients are similar where nearly one in five patients have “syncope of unknown origin” (11).

Syncope of unknown origin is less common in children under 5 years of age, in whom primary cardiac dysrhythmias, seizures, and breath-holding spells are the main considerations. Although the general categories of disorders resulting in syncope are similar in adults and children, the specific causes and evaluations differ between adults and children/infants.

The pathophysiology of syncope involves dysfunction of cerebral hemispheres or the reticular activating system in the brainstem, typically from an acute decrease in cerebral blood flow. Syncope occurs when cerebral blood flow decreases to less than 30% to 50% of baseline (12). This is most often the result of systemic hypotension, but may also be due to cerebral vasoconstriction or regional hypoperfusion of the central nervous system (CNS). Decreased cerebral perfusion impairs delivery of substrate (e.g., oxygen and glucose) to the brain. Less commonly, cerebral blood flow is adequate, but there is deficient substrate, as in hypoglycemia, carbon monoxide poisoning, severe anemia, or asphyxia.

CLINICAL PRESENTATION

Vasovagal syncope, also known as *neurocardiogenic, neurally mediated, vasodepressor,* and *reflex* syncope, is the most common cause of pediatric and adult syncope. It is responsible for about half of cases of pediatric syncope (11,13). Typical cases are individuals who faint while experiencing pain, anger, or fear (e.g., at the sight of blood), or while standing erect for a prolonged time in a warm environment (as in the military, a parade, or a religious service).

The mechanism of vasovagal syncope has been thought to be a vagally mediated reflex that causes bradycardia, and a decreased peripheral vascular resistance with venous pooling in the periphery resulting in hypotension from a loss of sympathetic tone. Decreased venous return leads to a relatively empty ventricle. Strong myocardial contractions against an empty ventricle stimulate the vagal reflex causing bradycardia, and sympathetic withdrawal results in decreased peripheral vascular resistance and a drop in arterial blood pressure. However, the occurrence of “vasovagal” syncope in patients with a heart transplant indicates that other mechanisms may also be responsible. Possibilities include neurohumorally mediated sympathetic inhibition, impaired responses in the peripheral vessels (affecting peripheral vascular

resistance), and abnormal CNS control mechanisms, or a combination of such factors.

Cardiovascular causes of syncope can be categorized into several groups: dysrhythmia, obstruction to flow, myocardial dysfunction, or vascular. The common pathophysiology is a decrease in cardiac output (CO) resulting in decreased cerebral perfusion. Cardiac syncope occurs when CO is decreased from inadequate stroke volume (SV) or an abnormal heart rate (HR), leading to inadequate filling of the ventricles.

Although *dysrhythmias* are a less frequent cause of syncope in pediatric patients than adults, this possibility should be in the differential because of the association with sudden death. Patients with heart disease, whether congenital or acquired, are at high risk for dysrhythmias and sudden cardiac death. Congenital heart disease is the number one cause of dysrhythmias resulting in syncope in pediatric patients. Most sudden cardiac deaths associated with dysrhythmias occur in pediatric patients who are status after corrective cardiac surgery, especially repair of tetralogy of Fallot, or a baffle (Mustard or Senning procedure) for transposition of the great vessels. Estimates of the incidence of sudden cardiac death with congenital heart disease are as follows:

Tetralogy of Fallot 2.5% to 10%

Eisenmenger syndrome = 10% to 47%

Ebstein anomaly = 2.5% to 20% (14).

Other cardiac disorders associated with dysrhythmias include Ebstein anomaly, arrhythmogenic right ventricular dysplasia, and cardiac tumors.

In patients with a structurally “normal” heart, syncope and sudden death can occur with Wolff–Parkinson–White syndrome (WPW), long QT syndrome, short QT syndrome, ventricular tachycardia, complete heart block, and the Brugada syndrome.

The diagnostic hallmark of WPW is a short PR interval and a delta wave. Supraventricular tachycardia results from reentrant conduction down the atrioventricular node and up the accessory pathway (Kent bundle). Rapid conduction over the Kent bundle can proceed to ventricular fibrillation and sudden death. An

electrophysiologic study with radio-frequency ablation is the recommended treatment.

The long QT syndrome is due to abnormal ventricular depolarization resulting in a prolongation of the refractory period. This can cause torsades de pointes with the potential to degenerate into ventricular fibrillation and sudden death. The long QT syndrome is characterized by QT interval prolongation. There are several forms of the long QT syndrome. The congenital types of long QT syndrome include the Romano–Ward syndrome and the Jervell and Lange-Nielsen syndrome. The Romano–Ward syndrome has an autosomal dominant inheritance, whereas the Jervell and Lange–Nielsen syndrome has an autosomal recessive inheritance and deafness. Acquired prolongation of the QT interval can be due to electrolyte abnormalities (hypocalcemia, hypokalemia), drugs/overdose, and increased intracranial pressure. Medications associated with prolongation of the QT interval include psychotropics (tricyclic antidepressants, phenothiazines), antihistamines, and promotility drugs (such as cisapride), especially in combinations with other medications (e.g., erythromycin and ketoconazole). The short QT interval is also associated with dysrhythmias and sudden death.

Bradyarrhythmias, which can cause syncope and sudden death, include complete heart block and sick sinus syndrome. Atrioventricular block may be congenital or acquired. Acquired causes are most common after cardiac surgery; but rheumatologic diseases, infections, and neuromuscular diseases (e.g., Lyme disease, acute rheumatic fever, endocarditis, diphtheria, myotonic dystrophy, certain forms of muscular dystrophy, and Kearns–Sayre disease) are other etiologies for complete heart block. Congenital heart block can occur as an isolated condition or with structural heart disease, especially defects of the atrioventricular septum, L-transposition of the great vessels, or ventricular inversion. Infants born to mothers with systemic lupus erythematosus may have complete heart block secondary to transplacental antibodies cross-reacting with fetal cardiac tissue.

Sinus node dysfunction most commonly occurs in patients who have undergone cardiac surgery, especially atrial surgery. These patients are also at risk for atrial arrhythmias (e.g., atrial flutter and atrial fibrillation). The combination of atrial flutter/fibrillation with a rapid ventricular response plus sinus node dysfunction can lead to syncope from hemodynamic compromise and is a harbinger for dysrhythmias and sudden death.

Ventricular tachycardia/fibrillation leading to syncope and sudden death can occur in patients with myocardial disease (such as myocarditis, cardiomyopathy, and myocardial ischemia) and with ventricular damage or scarring post cardiac surgery (even years after surgical repair).

The second category of cardiac syncope involves *obstruction to blood flow*. The classic example is hypertrophic obstructive cardiomyopathy. Aortic stenosis with outflow obstruction may cause syncope, anginal chest pain, and dyspnea on exertion. Severe coarctation of the aorta or severe mitral valvular disease can also present with syncope. Similarly, patients with primary pulmonary hypertension or severe pulmonic stenosis may develop syncope. Sudden death in Eisenmenger syndrome is probably due to a drop in blood flow from a sudden increase in pulmonary vascular resistance. Tumors such as an atrial myxoma causing decreased CO are a rare cause of cardiac syncope.

Myocardial disease is the third category of cardiac syncope and includes cardiomyopathies, myocarditis, myocardial ischemia (congenital from anomalous coronary arteries or acquired as in Kawasaki disease), and diseases infiltrating/destroying the myocardium such as amyloidosis or Chagas disease.

Vascular causes of syncope include aortic dissection, subclavian steal, thoracic outlet syndrome, and very rarely pericarditis leading to tamponade.

Respiratory diseases ranging from status asthmaticus to severe pneumonia or any cause of respiratory failure resulting in hypoxemia can cause syncope from decreased oxygen delivery to the brain. Posttussive or cough syncope, occurring after severe coughing, is due to decreased venous return (and, thus, decreased

CO) caused by the Valsalva maneuver. Cough syncope is a type of vasodepressor syncope. Pulmonary emboli (PE) while in the respiratory system exert their effect by obstruction of blood flow.

Other respiratory causes of syncope include breath-holding spells, which are unique to pediatrics, and hyperventilation. Hyperventilation syncope generally occurs when there is an emotional upset, pain, or anxiety, and is often associated with light-headedness, tachypnea, dyspnea, chest pain, and paresthesias. The pathophysiology is thought to be from decreased oxygen/glucose delivery to the brain caused by vasoconstriction of the cerebral arteries from the hypocapnia caused by hyperventilation.

Breath-holding spells are common, occurring in about 4.6% of children (15). Breath-holding spells usually begin between 6 to 18 months of age (with a range from the first week of life to 3 years) and end by 6 years of age in 90% of children. There are two types of breath-holding spells: cyanotic and pallid. Cyanotic spells are more common. Both spells are due to transient cerebral anoxia.

Typically, the cyanotic breath-holding spell is precipitated by the child's or infant's crying after being angered. The vigorous crying results in transient cerebral ischemia caused by (a) cerebral arterial vasoconstriction from hypocapnia, (b) hypoxemia from apnea, and (c) decreased CO from a prolonged Valsalva effect. The pallid breath-holding spell generally occurs after a painful or anxiety-producing incidence such as a minor fall. The transient cerebral ischemia occurring with the pallid breath-holding spell is due to an exaggerated vagal response to pain causing prolonged asystole or bradycardia. Breath-holding spells are a benign entity with no sequelae although they are commonly misdiagnosed as seizures.

Neurologic syncope can occur as a result of cerebral hypoperfusion from cerebral vasoconstriction (as with hyperventilation syncope) or from focal hypoperfusion of CNS structures. Cerebrovascular disease (more common in adults) could cause syncope, but usually there are other neurologic signs and symptoms. Other causes of syncope from focal hypoperfusion of CNS structures include subarachnoid hemorrhage, vasculitis (affecting cerebral vessels), CNS tumors, CNS trauma, and basilar artery migraine.

Psychiatric "disorders" are in the differential diagnosis of syncope. "Hysterical syncope" usually occurs before an audience, with no injuries occurring to the patient, and often is accompanied by dramatic moaning, gestures, and attention-seeking behavior with secondary gain.

The most common final diagnoses, according to a pediatric ED study of syncope in children and adolescents, were vasovagal (50%), orthostatic hypotension (20%) due to dehydration (15%) or anemia (5%), atypical seizure (7.5%), migraine (5%), and minor head trauma (5%) (13). A multicenter inpatient study of pediatric syncope from China reported the following causes of syncope; autonomic mediated reflex syncope (73%) consisting of vasovagal 43%, postural orthostatic tachycardia syndrome (POTS) 27%, situational 1.7%, and orthostatic hypotension 1.3%; followed by cardiac syncope 2.9%, neurologic syncope 2.1% consisting of seizure 1.9% and migraine 0.2%; psychiatric syncope 2.3%, metabolic syncope 0.8% comprised of hypoglycemia 0.4%, severe anemia 0.2% and hyperventilation syndrome 0.2%, and unknown origin 18.9% (11). Although it is likely that the ED and inpatient populations are different in these two studies, the most common cause of pediatric syncope in all age groups, whether ED or inpatient, is vasovagal with cardiac and neurologic syncope generally both $<5\%$.

DIFFERENTIAL DIAGNOSIS

Not all patients with a "transient loss of consciousness" are diagnosed with syncope (Table 235.1). In one study of adults presenting to an ED with an LOC, 12.3% of patients had a diagnosis other than syncope (1). The nonsyncope patients were categorized as either a disorder with LOC or a disorder mimicking an LOC. For the group with a disorder with LOC, hypoglycemia accounted for the majority of patients, with other diagnoses including transient ischemic attack, seizure, migraine, and other metabolic (hypoxia, hyperventilation) causes. Somatization disorders and drop attacks comprised the category of disorders mimicking an LOC (1). Another

ED study diagnosed seizures in 29% of patients who presented with a transient LOC (16). Comparable results were noted in a study of pediatric syncope patients with a neurologic condition diagnosed in 17.5% (atypical seizure 7.5%, migraine 5%, minor head trauma 5%) 13).

TABLE 235.1
Causes of Syncope in the Pediatric Patient

Vasodepressor (vasovagal, neurocardiogenic, neurally medicated, reflex)

- Triggers: pain, fear, prolonged standing, heat exposure
- Situational syncope: cough (posttussive), deglutition, micturition, defecation, hair grooming
- Carotid sinus sensitivity

Orthostatic (postural)

- Decreased intravascular volume: vomiting, diarrhea, hemorrhage; or relative hypovolemia: sepsis, extended bed-rest; drugs/toxins: diuretics, medications causing vasodilatation
- Postural orthostatic tachycardia syndrome

Dysautonomic syndromes: primary or secondary autonomic failure

- Primary autonomic failure

Multiple system atrophy: cerebellar/pyramidal, Parkinsonian

- Secondary autonomic failure

Central (CNS): multiple sclerosis, syringobulbia, CNS malignancies

Spinal: transverse myelitis, syringomyelia, spinal tumors

Peripheral nerve: rheumatologic/autoimmune diseases, AIDS, paraneoplastic syndrome, renal failure, familial dysautonomia, dopamine β-hydroxylase deficiency

Cardiovascular

1. Dysrhythmias: congenital or acquired
   - Bradyarrhythmias: sinus node disease, atrioventricular block (Stokes Adams syndrome)
   - Tachyarrhythmias: long QT syndromes, Wolf–Parkinson White syndrome, ventricular tachycardia, supraventricular tachycardia, torsades de pointes, ventricular fibrillation, arrhythmogenic right ventricular dysplasia
   - Postoperative congenital heart disease patients, certain congenital heart defects (tetralogy of Fallot, Ebstein anomaly, others) are especially high risk for dysrhythmias and sudden death
   - Pacemaker malfunction, AICD malfunction
2. Outflow obstruction
   - Hypertrophic obstructive cardiomyopathy, pericarditis with tamponade, severe aortic stenosis, pulmonary hypertension, prosthetic valve dysfunction, pulmonary emboli, some cyanotic congenital heart defects, severe coarctation, severe mitral stenosis, Eisenmenger syndrome, right ventricular dysplasia, cardiac tumor mass (atrial myxoma)
3. Myocardial disease/dysfunction
   - Cardiomyopathy, myocarditis, coronary artery abnormalities (congenital—anomalous coronary artery; or acquired—Kawasaki disease); rheumatologic/immunologic/vasculitis disorder: Lyme disease, amyloidosis, sarcoidosis; neuromuscular disorders: muscular dystrophy, others
4. Vascular
   - Aortic dissection, connective tissue disorders: Marfan disease, Ehlers–Danlos syndrome
   - Subclavian steal
   - Thoracic outlet syndrome

Neurologic

- Subarachnoid/epidural/subdural/intracerebral hemorrhage
- Transient ischemic attack/stroke
- Migraines: caused by spasm of vertebrobasilar arteries
- Neuropathies (see also dysautonomic syndromes)
- Seizures

Metabolic/endocrine

- Hypoglycemia

Respiratory/pulmonary

- Pulmonary emboli (see also cardiac)
- Cough (posttussive)
- Hyperventilation
- Breath-holding: cyanotic, pallid, mixed (autonomic dysregulation is presumed)
- Hypoxia
- Pulmonary disease or respiratory failure causing hypoxia
- Carbon monoxide poisoning, other toxins
- Severe anemia

Drugs

- Poisons, toxins
- Substance abuse, alcohol, opiates
- Prescription drugs: antidepressants (tricyclics, phenothiazines) antihypertensives (α- and β-blockers, hydralazine, ACE inhibitors, ganglionic blockers), vasodilators (calcium channel blockers, nitrates)

Psychiatric

- Hysteria

Thus, the main considerations for other "nonsyncopal" causes of a transient LOC are either a neurologic disease or a metabolic disorder. Neurologic disorders range from an acute neurologic event from a transient ischemic attack/cerebrovascular accident or hemorrhage/emboli to a migraine or seizures. Neuropathies can precipitate orthostatic (postural) hypotension and syncope. The differential illustrates the importance of the neurologic examination in any patient with syncope.

Hypoglycemia is the most common diagnosis in the metabolic/endocrine category of patients who may present with a transient LOC. Hyperventilation, drugs (alcohol/illicit drugs/prescription drugs), toxins, liver failure, renal failure, various congenital metabolic disorders, and carbon monoxide poisoning are also in the differential.

Seizures are often mistaken for syncopal events and vice versa. Brief tonic–clonic movements may occur with vasodepressor syncope. Akinetic seizures may be present like a syncopal episode. The history may help distinguish between syncope and a seizure. The following suggest a seizure, not syncope: focal neurologic signs, bowel/bladder incontinence, prolonged LOC or confusion, tongue biting, and a prodromal aura. With a syncopal episode, the period of unconsciousness is brief (only seconds) and has a rapid recovery to a normal mental status.

ED EVALUATION AND MANAGEMENT

The history and physical examination are the key components of the evaluation of the pediatric patient with syncope. After ruling out mimickers of pediatric syncope, such as seizures and breath-holding spells, the first consideration is to determine whether the etiology of the syncope is benign or life-threatening. With near syncope or presyncope, the syncopal symptoms resolve before LOC occurs. The evaluation of the near syncope patient, however, is similar to that of the syncope patient.

The history and physical examination should guide the ordering of laboratory and ancillary tests. If the history is pathognomonic, such as vasodepressor syncope (e.g., teenager who passed out while getting a routine immunization) or an infant with a breath-holding spell, further testing may not be necessary. If the history suggests orthostatic syncope due to dehydration from vomiting or diarrhea, checking electrolytes and providing intravenous fluids may be all that is needed.

The physical examination may provide clues to the diagnosis. Cardiac findings, such as a murmur, loud S2, the presence of a click, S3, or S4, suggest cardiac syncope. The presence of neurologic symptoms and signs may indicate CNS disease or a seizure. If there are differences in pulses and/or blood pressures between the extremities, consider the possibility of a dissecting aneurysm, a coarctation of the aorta, or subclavian steal. Focused testing in selected patients based on the history and physical examination is probably the most useful and cost-effective approach (17,18). Simple cost-effective tests may be helpful, such as abnormal orthostatic vital signs, supine tachycardia, or severe dizziness upon standing (3,13), suggesting orthostatic syncope; or hemoccult of the stool with melena, indicating gastrointestinal bleeding. A pregnancy test should be considered in female adolescents with syncope, as bleeding during pregnancy (as with ectopic pregnancy) can cause syncope. Patients with hypoglycemic symptoms can present with syncope, and thus a serum glucose or dextrostix might be useful, especially in a diabetic. When pallor is present or bleeding is suspected, a hematocrit is appropriate.

If cardiac syncope is being considered, an electrocardiogram (ECG) and chest roentgenogram are indicated. Additional evaluation such as an echocardiogram, Holter monitoring, pediatric cardiology consultation, or hospital admission may be warranted if cardiovascular syncope is strongly suspected and supported by the evaluation (3).

Many clinicians recommend an ECG in any pediatric or adult patients with syncope no matter the history to detect occult cases of cardiovascular syncope (4,7,17,18).

Routine computed tomography (CT) scans are usually not helpful, but a head CT scan may be indicated if neurologic signs/symptoms are present or new onset of seizures is a likely diagnosis. A chest CT scan or ventilation perfusion scan can be done if PE is a consideration. However, in the adolescent population a D-dimer may be useful to rule out PE and avoid unnecessary CT scanning. If orthostatic syncope from a dysautonomic syndrome is being considered, referral for tilt testing may be appropriate. The tilt test has been useful in selected pediatric patients, including those with "unexplained" syncope (19).

Several rules have been developed including the San Francisco Syncope Rule and the OESIL (Osservatorio Epidemiologico sulla Sincope nel Lazio) in order to predict which patients with syncope are likely to have an adverse outcome (2,20). However, these rules apply only to adults and prospective studies indicate clinical judgment performs as well as these rules (21,22).

CRITICAL INTERVENTIONS

- Obtain a clear history of the events prior to, during, and immediately after the syncopal event.
- Perform a thorough physical examination (particularly cardiac and neurologic), in addition to orthostatic vital signs.
- Perform a blood glucose in patients with altered level of consciousness and a urine pregnancy test in adolescent females.
- Obtain an ECG on patients with syncope, especially those with possible cardiac syncope to check for long QT syndrome, WPW syndrome, and other causes of cardiac syncope. A chest radiograph may be indicated in selected patients with ECG findings indicative of cardiomyopathy.
- Consider all patients with a history of cardiac disease (congenital or acquired, especially those who have had heart surgery) to have a potentially life-threatening dysrhythmia as the cause of their syncope.

DISPOSITION

Testing, referral, and the decision to admit to the hospital are generally guided by the findings on the history, physical examination, and ECG. Although most causes of syncope are benign, some are life-threatening, and syncope may be a warning sign of later sudden death. Thus, patients with cardiac syncope typically require referral and admission. Patients experiencing vasopressor syncope or breath-holding spells may be discharged home without additional testing. Patients with orthostatic syncope from dehydration can usually be treated with intravenous fluids in the ED and then discharged home. Patients with a dysautonomic syndrome generally need to be referred.

Common Pitfalls

- Failure to differentiate syncope from seizures and breath-holding spells.
- Failure to recognize potentially life-threatening causes of syncope.
- Failure to identify the high-risk patient (e.g., the patient with congenital heart disease or a history of cardiac surgery) and refer or admit to the hospital.
- Failure to perform a pregnancy test on sexually active adolescent females.

CHAPTER 236

Seizures

Craig R. Warden and Beech S. Burns

A seizure in a child can be a dramatic event, provoking fear and panic in parents and caregivers, and not surprisingly frequently presents to the emergency department (ED). A seizure is a series of excessive, abnormal electrical discharges of cerebral neurons producing transient involuntary alterations in consciousness, motor activity, behavior, and/or autonomic regulation. Seizures affect 4% to 6% of children by age 16, and are the most common childhood neurologic disorder (1).

During seizure activity, consumption of oxygen and glucose is increased in cerebral tissues. Early physiologic changes include hypertension, hyperglycemia, and hypoxemia. With subsequent or prolonged seizure activity, progressive lactic acidosis, rhabdomyolysis, hyperkalemia, hyperthermia, and hypoglycemia may develop, possibly leading to permanent neurologic damage.

Most childhood seizures are brief and isolated and have a good outcome in both the short and long terms. At the other extreme, status epilepticus (SE), as historically defined, is recurrent or continuous seizure activity lasting longer than 30 minutes without recovery of baseline mental functioning. However, many experts have argued that continuous or recurrent seizure activity lasting longer than 5 minutes should be considered SE. Current evidence suggests that seizures that do not resolve spontaneously over this brief period are unlikely to do so and that more aggressive antiepileptic drug therapy is indicated at that point (2). SE is one of the most common neurologic emergencies encountered in children, and up to 10% of children with new onset seizures will present in SE

(3). Given their frequency, the ED physician should be familiar with all aspects of seizure management, including initial stabilization, primary investigation of cause, acute management, and disposition.

CLINICAL PRESENTATION

Broadly, seizures are classified as either generalized or partial. Generalized seizures may be convulsive or nonconvulsive and are almost always attended by an altered level of consciousness. If the seizure has a motor component it is bilateral, as both cerebral hemispheres are involved. Partial seizures, which originate in one cerebral hemisphere, may be simple (without affecting consciousness) or complex (associated with impaired mental status), and may manifest in a variety of ways. These include tonic, clonic, tonic–clonic, or myoclonic motor activity; sensory distortions or hallucinations; autonomic symptoms such as sweating and piloerection; repetitive, stereotyped movements; or isolated behavioral changes, such as continuous crying or bicycling movements seen in infants (4). See Table 156.1 in Chapter 156.

By the time the patient is in the ED, many seizures have spontaneously ceased. At this stage, the most important task of the ED physician, after a brief primary survey, is to obtain a thorough history and physical. At this time the physician can determine whether a postictal phase is present, whether loss of bowel and/or bladder control occurred, or whether a focal neurologic deficit remains. This will help differentiate true seizures from alternative diagnoses presenting similarly. Furthermore, such information can help determine when further workup is warranted. For example, a hemiparesis (Todd paralysis) or other focal neurologic deficit is an important localizing sign suggesting that the seizure had a focal component. However if the focal deficit is new and persists, neuroimaging is indicated to identify a potential CNS lesion.

When a child presents with concern for seizure, the most important initial task is to determine whether there is ongoing seizure activity. If seizure activity is continuing, managing the ABCs and terminating the seizure are the first priorities.

DIFFERENTIAL DIAGNOSIS

Seizures have many potential causes, which vary with age (Table 236.1). Rather than a litany of laboratory tests, a detailed history of the event from a witness is the single most important element to accurately determine etiology. This history can then guide further diagnostic testing. A detailed history can also be the key to determining whether the child has actually had a seizure, as other childhood conditions can be mistaken for epileptic events. These disorders can be classified into one of three categories based on presentation: (1) sudden loss of consciousness (LOC), (2) paroxysmal movements, or (3) sudden change in behavior.

TABLE 236.1
Acute Causes of Seizures by Age

Neonatal

Congenital CNS abnormalities

Hypoxic–ischemic CNS insult

Intracranial hemorrhage

Intrauterine drug exposure/drug withdrawal

Metabolic disorders (e.g., hypoglycemia, hyponatremia, hypernatremia, hypomagnesemia, hyperphosphatemia, hypocalcemia)

Inborn errors of metabolism

Hypertension

Infections/sepsis

Epilepsy (e.g., infantile spasms)

Pyridoxine deficiency

Benign familial neonatal seizures/benign idiopathic neonatal seizures ("fifth day fits")

Early Childhood

Past birth-related injury

Febrile seizures (6 mos to 5 yrs)

Meningitis/encephalitis

Metabolic disorders

Neurocutaneous syndromes

Cerebral degenerative disorders

Tumors

Head trauma (shaking or direct injury)

Epilepsy (± medication noncompliance)

Children and Adolescents

Head trauma

Meningitis/encephalitis

Epilepsy (± medication noncompliance)

Cerebral degenerative disorders

Tumors

Idiopathic

Any Age Group

Ventriculoperitoneal shunt malfunction or infection

Toxins (PLASTIC)

- *P*esticides, phenothiazines, phencyclidine
- *L*idocaine, lindane, lithium
- *A*lcohol, amphetamines, antihistamines, antidepressants, anticholinergics
- *S*alicylates
- *T*heophylline
- *I*nsulin, isoniazid, Inderal
- *C*amphor, caffeine, carbon monoxide, cocaine

CNS, central nervous system.

Disorders with sudden LOC include breath-holding spells, syncope, cardiac dysrhythmias, and complicated migraine. In contrast to true seizures, in these conditions a postictal state is rare. The LOC in vasovagal syncope is brief and recovery is rapid, though these episodes may occasionally be accompanied by a brief generalized seizure. With complicated migraine, LOC may be associated with or preceded by blurred vision, blindness, dizziness, or loss of postural tone. Breath-holding spells, typically seen in young children between 6 months and 6 years, are associated with emotional upset or minor trauma and result in LOC. They are differentiated from seizures by the characteristic precipitating stimulus and color change preceding LOC. Disorders involving paroxysmal movements include tics, shuddering attacks, benign sleep myoclonus, and pseudoseizures. Shuddering attacks typically begin in infancy and are characterized by rapid tremors of the entire body, which may occur up to 100 times a day. They are thought to be benign but EEG is indicated to help differentiate them from true seizures (5). Psychogenic nonepileptic seizures (formerly pseudoseizures) are episodes of motor, sensory, or cognitive disturbance that are not due to central nervous system (CNS) dysfunction but mimic epileptic seizures. They can be difficult to distinguish from true seizures, particularly as they often occur in patients with true epilepsy. However, clues that an episode is nonepileptic include asynchronous motor movements, lack of self-injury or incontinence, and forced eye closure. Ultimately, video EEG monitoring may be required for definitive diagnosis. Lastly, disorders with sudden behavioral changes may mimic seizures. One such example is night terrors, wherein the school-age child wakes from sleep with intense fear and autonomic arousal; the child typically does not remember the event (4).

ED EVALUATION

The history and physical examination are the most useful tools in the ED evaluation. The history should focus on a detailed description of the seizure including seizure duration, type of seizure (focal or generalized), associated LOC, presence of incontinence or cyanosis, length of postictal period, any postictal neurologic abnormalities,

and, for patients with a known seizure disorder, whether the current seizure is different or the frequency has increased. Further history should focus on potential causes: trauma, infection, recent immunization, presence of a cerebrospinal fluid (CSF) shunt, intoxication, a history of seizures, anticonvulsant use and compliance, or use of the ketogenic diet. The history should include any prehospital observations and treatment by either caretakers or emergency medical service (EMS) providers. The administration of benzodiazepines by caretakers or EMS providers may explain a prolonged postictal phase (7).

The physical examination should focus on signs of trauma (including retinal hemorrhages), increased intracranial pressure (ICP), focal neurologic abnormalities, and meningeal irritation. In addition, one should assess for hepatosplenomegaly for possible metabolic or glycogen storage disease and the skin for café-au-lait spots (neurofibromatosis), vitiliginous lesions (tuberous sclerosis), or port-wine stains (Sturge–Weber syndrome).

Laboratory testing should be guided by the history and examination. A rapid bedside glucose should be done on all seizure patients; however, serum electrolytes, calcium, magnesium, ammonia, complete blood count, and urine toxicology have been shown in several studies to have a low yield in patients without identifiable risk factors (1). They should therefore be reserved for patients with a significant pretest probability of an acute electrolyte disturbance. In patients on chronic anticonvulsants, appropriate serum drug levels should be obtained.

With the exception of the neonate, a lumbar puncture is not indicated for the child with a seizure who has no other clinical findings supportive of meningitis. Emergent head CT is also not routinely warranted in patients presenting with a first afebrile seizure (1). However, emergent neuroimaging should be strongly considered in the patient who demonstrates persistent focal deficits on neurologic examination, has signs of increased ICP, is younger than 6 months, has a ventriculoperitoneal shunt, presents in SE, is immunocompromised, has traveled to an area endemic for cysticercosis, has suspected cerebrovascular disease, has a bleeding

disorder or hypercoagulable state (including sickle cell disease), or in whom head trauma is suspected (8,9). If emergent neuroimaging is not required, brain magnetic resonance imaging is the preferred modality for new-onset seizure in children and can be arranged on an outpatient basis. EEG is rarely required emergently, with the notable exceptions of refractory SE or when a diagnosis of nonconvulsive SE is being considered (10).

ED MANAGEMENT

Seizure activity upon arrival in the ED should be considered SE until further history can be obtained, and the main priorities should be maintenance of airway, breathing, and circulation, followed by interventions to stop the seizure. A brief history should focus on finding an acute cause of the seizure, such as trauma, infection, or intoxication, along with a previous history of seizures and known anticonvulsant use. A rapid physical examination should search for signs of trauma, increased ICP, and meningeal irritation. If meningitis is a concern, appropriate antibiotics should be given expeditiously.

Benzodiazepines are the drugs of choice for initial management of all seizures in children older than 28 days. Lorazepam may be preferred because of its long half-life, though diazepam and midazolam are also effective choices. Midazolam has become more frequently utilized in prehospital and ED settings since it may be delivered intranasally, buccally, or intramuscularly, which is a distinct advantage in critically ill pediatric patients in whom intravenous access may be challenging (8). Diazepam can be given rectally, and a viscous solution for rectal administration called Diastat is available for use at home. Important side-effects of benzodiazepines are respiratory depression and, in higher doses, hypotension.

Fosphenytoin or phenytoin has traditionally been used as a second-line agent if seizure activity continues after benzodiazepine administration. Fosphenytoin (a prodrug of phenytoin) is often preferred for use in children because it is less likely to cause hypotension with IV infusion or tissue necrosis after accidental

infiltration. Fosphenytoin (like midazolam) can be given intramuscularly if vascular access has not been established.

In the recent years, levetiracetam has been increasingly employed in the management of SE, most frequently as a second-line agent. It has a favorable side-effect profile and has been demonstrated to be safe in children as young as 6 months of age (25). Valproate has also demonstrated utility as a second-line drug in pediatric patients, with the advantage that it lacks adverse effects on cardiorespiratory function (12). Phenobarbital continues to be used as a second- or third-line agent in pediatric SE, though caution should be exercised as there is a significant risk of respiratory depression with phenobarbital, particularly when given after benzodiazepines.

In 25% of patients with SE, seizures will continue despite initial therapies. In these cases, SE is considered refractory and induction of general anesthesia is often indicated. Commonly utilized agents include midazolam, pentobarbital, and propofol, and limited evidence suggests that none of these agents is clearly superior to the others (13). See Table 236.2 for dosing information of available medications.

TABLE 236.2
Medications Used in the ED for Seizures and Status Epilepticus

Use	Drug	Route/Dosage/Max Dose	Adverse Effects
First-line agents	Midazolam	IV: 0.1 mg/kg, up to 10 mg	Loss of airway control, hypoventilation
		IM: 0.2 mg/kg, up to 10 mg	Hypotension: rare
		IN: 0.2–0.4 mg/kg, up to 10 mg	
		Buccal: 0.2–0.5 mg/kg, up to 10 mg	
	Diazepam	IV, IM: 0.2–0.3 mg/kg, up to 10 mg	Loss of airway control, hypoventilation
		PR: 0.5 mg/kg, up to 20 mg	Hypotension: rare
			PR: erratic absorption
			IM: sterile abscess
	Lorazepam	IV: 0.1 mg/kg, up to 4 mg	IM: erratic absorption, accumulation of drug with multiple doses
		IM: 0.2 mg/kg	
Second-line	Phenytoin	IV: 20 mg/kg over 30–45 min, up to 1,000 mg	Hypotension and arrhythmias with rapid infusion
	Fosphenytoin	IV: 20 mg PE/kg over 15 min, up to 1,000 mg	Expensive
		IM: same, several sites needed	Less effective for seizures due to toxins/drugs
	Levetiracetam	IV: 20–30 mg/kg over 15 min, up to 2,500 mg	Few side effects, limited evidence for use
	Valproic acid	IV: 20–40 mg/kg over 10 min	Hepatotoxicity, pancreatitis, thrombocytopenia
Third-line	Phenobarbital	IV: 20 mg/kg over 30 min	Loss of airway control, hypoventilation, hypotension, prolonged obtundation
Fourth-line	Pentobarbital	IV: 5–15 mg/kg slow bolus then 1–3 mg/kg/hr	Loss of airway control, hypoventilation, hypotension, prolonged obtundation
	Midazolam	IV: 0.1–0.2 mg/kg slow bolus then 0.06–0.12 mg/kg/hr (1–2 µg/kg/min) titrate by 0.06 mg/kg/hr (1 µg/kg/min) every 10 min as needed	Loss of airway control, hypoventilation, hypotension, prolonged obtundation
	Propofol	IV: 2.5–3.5 mg/kg over 30 sec, then 0.2–0.3 mg/kg/min	Hypotension; contraindicated in ketogenic diet; not recommended in patients <3 yrs of age

PE, phenytoin equivalents; IV, intravenous; IM, intramuscular; PR, per rectum.

CRITICAL INTERVENTIONS

- The following protocol is suggested to manage SE (7,11–16):

At 0 to 5 minutes

- Maintain airway, give oxygen, support ventilation, and consider cervical spine immobilization for trauma patients.
- Obtain IV access, check bedside glucose, and send blood samples for electrolytes, complete blood count, glucose, and anticonvulsant levels, as appropriate.
- Monitor vital signs, pulse oximetry, end-tidal CO_2, and electrocardiography.
- Administer first dose of benzodiazepine (see **Table 236.2**) IV. If delay in obtaining IV access, administer midazolam or lorazepam IM, diazepam PR, or midazolam IN/buccal.
- Consider intravenous glucose 2 mL/kg of D_{25} (use D_{10} solution in newborns) for documented hypoglycemia only, and pyridoxine (50–100 mg IV) for neonates (or for isoniazid overdose).

At 5 to 15 minutes, if seizure continues

- Administer second dose of benzodiazepine (see **Table 236.2**).
- Start loading dose of phenytoin/fosphenytoin versus levetiracetam versus valproate, consider phenobarbital for neonates (see **Table**

236.2).
- Search for reversible causes of seizures (trauma, toxins, shunt malfunction, and electrolyte abnormalities) and initiate appropriate management.
- Continue monitoring of VS, including pulse oximetry and now core temperature for hyperthermia.

At 15 to 30 minutes, if seizure continues
- Start loading dose of phenobarbital versus levetiracetam versus valproate, if not already used (see **Table 236.2**).
- Reevaluate airway and strongly consider need for intubation.
- Initiate contact with referral pediatric intensive care unit (PICU) and transfer patient if necessary.
- Continue search for reversible causes of seizure and initiate appropriate management.
- Check electrolyte results; consider need for intravenous hypertonic saline for symptomatic hyponatremia.

At >30 minutes, if seizure continues
- Consider additional phenobarbital/levetiracetam/valproate.
- Consider consultation with pediatric neurologist. Continuous EEG monitoring needed.
- Consider continuous pentobarbital, midazolam, or propofol infusions, in consultation with neurology/anesthesiology.
- Intubate now if not previously done.
- Consider central venous access for multiple infusions including possible vasopressors and central venous pressure monitoring. Consider continuous arterial pressure monitoring.

At beyond 60 minutes, if seizure continues
- Begin additional continuous infusion regimen with pentobarbital, midazolam or propofol, or general anesthesia while awaiting transfer or admission to PICU.

DISPOSITION

Children with first-time seizures without SE can be followed up as outpatients if they appear well, the parents are comfortable with outpatient management, and follow-up can be assured. These children frequently do not require maintenance anticonvulsant

therapy, but the decision to start therapy, and which agent to use, should be done in consultation with a pediatric neurologist and the primary care physician (1). Hospital admission is reserved for children with a prolonged seizure or SE, even if successfully treated in the ED. Additional high-risk factors for early recurrence of seizures that may justify admission are age younger than 1 year, multiple seizures within 24 hours, and children requiring treatment in the ED (17). Children requiring intubation and ventilatory support or those with refractory SE should be transported to a tertiary care facility with a PICU and pediatric subspecialists.

SPECIAL CONSIDERATIONS

Febrile Seizures

Febrile convulsions are the most common form of seizures in childhood, occurring in 2% to 5% of children. Febrile seizures are defined as a seizure in association with a febrile illness, without CNS infection, previous afebrile seizures, known brain disorder, or electrolyte imbalance. They usually occur between the ages of 6 months and 5 years; the peak incidence is at approximately 18 months of age. Febrile seizures are classified as simple or complex. A febrile seizure is complex if it is focal, lasts longer than 15 minutes, or multiple (more than one seizure in 24 hours). The majority of febrile seizures are simple, and by definition are brief, isolated, and generalized (18). The pathophysiology of febrile seizures remains unclear, though viral infections, immunizations, and genetic predisposition have been implicated (19). Mortality is extremely rare, and there are no differences in cognitive abilities after a febrile seizure, even when it is prolonged (20).

To diagnose a febrile seizure, meningitis, encephalitis, electrolyte abnormality, and other acute neurologic disease must be ruled out. However, most of these can be eliminated by a careful history and physical examination. There has been much debate over whether lumbar puncture is a necessary diagnostic test in children with simple febrile seizures. In 2011, the American Academy of Pediatrics revised its guidelines for the evaluation of children with simple

febrile seizures who are between the ages of 6 months and 5 years (18). According to these guidelines, a lumbar puncture should be considered in all infants aged 6 to 12 months who have not received recommended vaccinations for *Streptococcus pneumoniae* or *Haemophilus influenza* type b or when immunization status cannot be determined. It should also be considered in all children aged 6 months to 5 years who have been pretreated with antibiotic therapy. Children who present with simple febrile seizures who satisfy neither of these conditions do not require lumbar puncture; indeed, patients with simple febrile seizures have the same risk of serious bacterial illness, including meningitis, as matched febrile patients without seizures (18). Further, neuroimaging of any kind is not routinely required, and additional routine laboratory studies are of limited value. Other than evaluation and treatment of the underlying cause of the fever, the majority of cases require only reassurance and education of parents about febrile seizures.

The evaluation of a child with complex febrile seizures (CFS) is less straightforward and definitive guidelines do not exist. Therefore, evaluation must be tailored to the clinical situation. Generally, acute bacterial meningitis does not present with CFS as its sole manifestation. A study in 2011 included 340 patients with CFS who underwent lumbar puncture; of these patients, 3 met criteria for acute bacterial meningitis. One patient was unresponsive at presentation, a second had a bulging fontanel and apnea, and the third was a 7-month old with recurrent seizures. Two of the three patients presented before introduction of the conjugated pneumococcal vaccine. Acute bacterial meningitis, then, is very rare in patients with CFS in the absence of other suggestive features (21). Lumbar puncture should be considered in patients who present with prolonged seizures or focal features. Routine neuroimaging is not warranted, though may be indicated in the child who presents with an abnormal physical examination or SE (22).

Neonatal Seizures

Due to an immature nervous system and insufficient myelination, neonatal seizures are often clinically subtle. They may manifest as

apnea, eye deviations, abnormal chewing movements, or abnormal extremity movement such as “bicycling.” Less frequently, in contrast with the coordinated tonic–clonic movements often seen in older children, seizures may present as asynchronous clonic movements involving one or more extremities, tonic movements, or brief myoclonic jerks (23). Occasionally, an excessively “jittery” baby may be thought to be having seizures, but these movements can often be suppressed with gentle restraint. Crucially, in contrast to older patients, most neonatal seizures are provoked by an underlying abnormality, and a vigorous search for an etiology is appropriate. The most common etiology of neonatal seizures is hypoxic–ischemic encephalopathy from a perinatal anoxic insult, which usually presents within the first 48 hours of life. Intracranial hemorrhage accounts for a sizable number of cases, while inborn errors of metabolism, sepsis, metabolic derangements, CNS malformations, and toxins are less frequent etiologies (24). Pyridoxine deficiency is an autosomal recessive disorder that is a rare cause of neonatal seizures but does not readily respond to the usual treatment of SE; it is eminently treatable with supplemental pyridoxine and should be thought of when seizures are resistant to initial therapy. There are two benign neonatal seizure disorders that are diagnoses of exclusions: *Benign familial neonatal convulsions,* which present in the first 3 days of life in patients with a strong family history of epilepsy or neonatal seizures, and *benign idiopathic neonatal convulsions* (“fifth day fits”) that peak on the fifth day of life and consist of multifocal clonic seizures and apnea. Both may require therapy but overall have a favorable prognosis (25).

The workup of neonatal seizures should always include an imaging study (magnetic resonance imaging, cranial ultrasound, or CT). Laboratory workup should include electrolytes (including magnesium, calcium, and phosphate), bedside glucose determination, and toxicology studies when indicated. If an inborn error of metabolism is suspected, blood studies for amino acids, lactate, pyruvate, and ammonia, and urine for organic acids are indicated. Sepsis is always high on the differential in any sick neonate, and the workup generally includes a complete blood count with differential,

blood culture, urinalysis and urine culture, and CSF testing (including consideration of tests for herpes simplex).

The management of neonatal seizures is initially the same as for older infants and children, with attention to the ABCs and to terminating the seizure. Historically, first-line therapy for neonatal seizures has been phenobarbital, though fosphenytoin has also been frequently utilized. There is little evidence for the use of benzodiazepines in neonates and concerns exist regarding their long half-life and associated respiratory depression; however, midazolam has shown promise in the treatment of neonatal SE. Levetiracetam has seen more frequent use as an off-label therapy for neonatal seizures, given its favorable side-effect profile and the limited efficacy of other agents (24,25). Pyridoxine should be considered if seizures are refractory to first-line agents. Perhaps the most effective therapy for neonatal seizures is identifying the underlying etiology and correcting the derangement. Therefore, electrolyte and glucose abnormalities should be aggressively sought and treated appropriately. Most neonates with seizures are initially treated with antibiotics for potential sepsis, and all are admitted to an appropriate monitored bed.

Common Pitfalls

- Failure to address airway, breathing, and circulation as the first priority in SE.
- Failure to expeditiously treat ongoing SE with loading doses of anticonvulsants if benzodiazepines have not been effective.
- Performing diagnostic tests on febrile seizures when not indicated.
- Failure to consider child abuse in young children.

CHAPTER 237
Altered Mental Status

S. Margaret Paik and Mark A. Hostetler

Altered mental status (AMS) is a commonly used term for any change in the level of consciousness (LOC). *Lethargy, obtundation, delirium, stupor,* and *coma* are often used interchangeably but are not synonymous. These conditions occur along a continuum, with lethargy indicating the least amount of dysfunction and coma indicating the most (Table 237.1) (1).

TABLE 237.1
Terms Used to Describe Altered Mental Status

Term	Description
Lethargy	Difficulty maintaining a state of wakefulness but arouses to vocal stimuli
Obtundation	Blunted state of alertness when responding to stimulation other than pain
Delirium	Decompensation in mental status characterized by one or more of the following: disorientation, trepidation, misinterpretation of sensory stimuli, or hallucinations
Stupor	Responsive only to painful stimuli that is forceful and continuous
Coma	Unresponsive to painful stimuli

CLINICAL PRESENTATION

Coma occurs if there is either bilateral cerebral dysfunction, injury to the ascending reticular activating system (ARAS), or both. The ARAS within the brainstem activates the cerebral cortex, resulting in wakefulness, attention, and a normal LOC (2).

Encephalopathy is a state of global brain dysfunction with at least two of the following symptoms: altered LOC, altered behavior, or seizures. Acute mental status changes and cerebrospinal fluid pleocytosis are most often seen in individuals with acute encephalitis.

Structural abnormalities, as seen with trauma or tumors, can lead to compression of the ARAS and produce focal deficits. Supratentorial lesions can cause compression of underlying structures with shifting of the intracranial contents and herniation (3). In uncal herniation, an expanding lesion in the temporal fossa or temporal lobe displaces the uncus and hippocampal gyrus toward the midline and the edge of the tentorium. The initial complaint may be of headache with subsequent progression to AMS. A unilateral dilated pupil is most often noted on the ipsilateral side of the lesion. Further expansion of the lesion results in increased intracranial pressure (ICP), decerebrate posturing, and transtentorial or central herniation. Central or transtentorial herniation occurs with caudal displacement of the thalamus and hypothalamus through the foramen magnum, into the posterior fossa. Compression of the brainstem results in abnormal posturing, abnormal breathing patterns, and abnormal pupils, ranging from small and reactive to midposition and fixed (4,5). Abrupt onset of coma coupled with a rapidly deteriorating clinical course suggests an acute subtentorial lesion such as cerebellar tonsillar herniation.

In pediatric patients, the majority of cases of coma are due to nonstructural causes (infection, toxic ingestion, metabolic abnormalities) and result in bilateral cerebral hemisphere dysfunction with global but symmetric deficits. In general, confusion, stupor, and obtundation precede any motor deficits. Pupillary responses remain preserved, but the respiratory rate and pattern may be altered (3).

DIFFERENTIAL DIAGNOSIS

Several different schemas have been used in the evaluation of a patient with AMS. The AEIOU-TIPS coma mnemonic (see Table

237.2) (4) is often used for adult patients with AMS. Although clinically useful as a starting point, several diagnoses specific to the pediatric patient must be highlighted. The most notable are child abuse, infection, intussusception, metabolic disorders, accidental ingestions, and seizures.

TABLE 237.2
Pediatric Altered Mental Status: The "AEIOU–TIPS" Mnemonic

A	Alcohol
	Abuse (nonaccidental trauma)
E	Encephalopathy (infectious, metabolic, toxic, Reye syndrome)
	Electrolyte abnormalities (hypoglycemia, hypo- or hypernatremia, hypocalcemia)
	Endocrinopathy (inborn error of metabolism, congenital adrenal hyperplasia)
I	Infection (meningitis; encephalitis; sepsis; focal, such as brain abscess)
	Intussusception
	Inborn errors of metabolism (fatty acid oxidation disorder, urea cycle defect)
O	Overdose (carbon monoxide, opiates, sedatives)
U	Uremia (hemolytic uremic syndrome, renal failure, Reye syndrome)
T	Trauma (intracranial hemorrhage)
	Tumor
	Toxins (lead)
I	Insulin (diabetic ketoacidosis, ketotic and nonketotic hypoglycemia)
P	Psychogenic (pseudoseizure, conversion disorder)
S	Seizure (neonatal, atypical, complex)
	Shock
	Shunt malfunction (increased intracranial pressure, infection)
	Stroke (arteriovenous malformations, hemoglobinopathies)

Abuse or Trauma

Child physical abuse (nonaccidental trauma) is the primary cause of serious head injury in infants (see Chapter 290). Findings consistent with the diagnosis of "shaken-baby syndrome" or "shaken-impact syndrome" include subdural hematoma, subarachnoid hemorrhage, retinal hemorrhage, as well as rib and long bone fractures.

Discrepancies between the history and the findings on the physical examination should alert the physician to the possibility of physical abuse. Children may present with AMS and a paucity of external physical findings on the initial evaluation. Retinal hemorrhages seen on the fundoscopic examination are suspicious for physical abuse. Previously, it was postulated that retinal hemorrhages could be a result of vigorous resuscitative efforts, but studies do not support this theory (6). Evidence of papilledema is suggestive of increased ICP and should alert the physician to the possibility of child abuse (6,7).

Infection

Infection must always be considered as a potential cause of AMS. This is especially true in younger patients with limited communications skills. It is also vital to consider infection in immunocompromised patients with abnormal behavior or altered alertness. Clues such as fever, ill contacts, or associated symptoms such as headache, photophobia, or meningismus may be helpful. Nevertheless, even in their absence it is important to rule out occult infection when alternative diagnoses do not present themselves.

Intussusception

Intussusception occurs most often in children between the ages of 3 and 12 months, with a male to female ratio of 4:1 (see Chapter 270). Although patients typically present with complaints of abdominal pain and vomiting, up to 10% of infants present solely with a depressed LOC. It is postulated that endogenous opioids are released from the bowel wall. The “classic triad” of colicky abdominal pain, vomiting, and currant jelly stools is seen infrequently (<25% in some reports) (8,9).

Metabolic Disorders

Inborn errors of metabolism should be considered in a young infant with a history of vomiting, poor feeding, failure to thrive, and AMS.

These are divided into two groups: (1) those with metabolic acidosis and (2) those with hyperammonemia. Seizures, especially in the neonatal period, may be associated with the initial presentation of a metabolic disorder. While these disorders most frequently manifest during the neonatal period, later childhood presentations are possible, sometimes triggered by a mild viral illness. Specific laboratory studies including serum pyruvate, lactate, and ammonia may be helpful in distinguishing between disorders causing acidosis versus hyperammonemia. There have been improvements in the recognition and diagnosis of fatty acid oxidation disorders, particularly medium-chain acyl-coenzyme-A–dehydrogenase deficiency (MCAD), which many believe mimic most of the symptoms associated with Reye syndrome. Early identification and treatment of these children can prevent long-term neurologic sequela (4,10).

Accidental Ingestions

AMS caused by lead encephalopathy is still seen in children, especially those living in older buildings or those who live near construction sites. Lead encephalopathy can present with a prodrome of vomiting, abdominal pain, and fatigue. Ingestion of paint chips or dust coating the surface of objects put into a child's mouth can cause a rapid and acute rise in the serum lead level resulting in AMS. Symptoms include seizures, cranial nerve palsy, lethargy, and coma (11).

Other ingested substances associated with AMS are listed in Table 237.3 (1). Many substances can cause AMS in small amounts, and some of these can be truly toxic or deadly. All exposures should be reported to the regional poison control center.

TABLE 237.3
Substances Associated with Altered Mental Status

Substances Associated with Altered Mental Status	
Alcohols	Heavy metals
Anticholinergics	Insulin
Amphetamines	Lithium
Anticonvulsants	Lysergic acid diethylamide (LSD)
Barbiturates	Narcotics
Carbon monoxide	Nonsteroidal anti-inflammatory drugs
Clonidine	Nicotine
Cocaine	Organophosphates
Cyclic antidepressants	Phencyclidine (PCP)
γ-Hydroxybutyrate (GHB)	Theophylline

Seizures

Neonatal seizure patterns vary greatly between older infants and children (see Chapter 236). The incompletely myelinated neural pathways of neonates are incapable of propagating true tonic–clonic seizures. In addition, many newborns thought to be having generalized tonic–clonic movements are actually exhibiting tremulousness. More typical of neonatal seizure are apnea with tonic stiffening, focal clonic movement, myoclonic jerks, lateral or upward tonic deviation of the eyes, or patterned stereotypical behavior such as paroxysmal laughing or chewing (3).

DIAGNOSTIC APPROACH

The initial evaluation of a child with AMS begins with attention to the ABCs: ensuring the protection and patency of the airway, adequacy of breathing, and maintenance of a normal circulatory status. During the subsequent secondary evaluation are a number of important clues in the history and physical examination. An effort should be made to obtain at least an AMPLE history: *A*llergies, *m*edications, *p*ast medical history, *l*ast meal, and *e*vents of recent occurrence. Specifically note if the history includes any possible ingestions or exposures, vomiting, trauma, fever, or unusual behavior.

The infant's open anterior fontanelle can be palpated to gain a rough sense of ICP and hydration. It is helpful to smell the patient's

clothes and breath to discover clues to possible ingestions or exposures. The child should be completely undressed, viewed, rolled, and palpated from head to toe and from front to back to evaluate for any signs of trauma, with specific attention to nonaccidental trauma to the head, abdomen, or extremities. The abdomen should be assessed for any evidence of hepatosplenomegaly, mass, or overall tenderness. The skin should be examined for rashes or bruising, and the extremities should be examined for tone and capillary refill (1,3,4).

The child's LOC can be assessed by using either the AVPU (alert, responds to verbal stimuli, responds to painful stimuli, unresponsive) or the Glasgow coma scale (GCS). A modified scoring system has been developed for use in nonverbal pediatric patients (Table 237.4) (12,13).

TABLE 237.4
Pediatric Glasgow Coma Score and Glasgow Coma Score

Best Response	Score	Pediatric GCS	GCS
Eye	1	No eye opening	No eye opening
	2	Eye opening to pain	Eye opening to pain
	3	Eye opening to speech	Eye opening to verbal command
	4	Eyes open spontaneously	Eyes open spontaneously
Verbal	1	No verbal response	No vocal response
	2	Inconsolable, agitated	Incomprehensible sounds
	3	Persistent crying or screaming	Inappropriate words
	4	Cries but consolable	Confused conversation
	5	Smiles, interactive	Orientated
Motor	1	No motor response	No motor response
	2	Extension to pain	Extension to pain
	3	Flexion to pain	Flexion to pain
	4	Withdraws from pain	Withdraws from pain
	5	Localizing pain	Localizing pain
	6	Obeys commands	Obeys commands

GCS, Glasgow coma score.

Abnormal respiratory patterns can imply either a metabolic insult or a structural lesion. In Cheyne–Stokes respiration, periods of hyperpnea alternate with apnea, with the hyperpneic phase lasting longer than the apneic phase. This may indicate either a lesion deep inside both cerebral hemispheres (bilateral cerebral infarction) or a metabolic encephalopathy (e.g., due to hypoglycemia) (1).

Abnormal pupillary responses may help to localize the level of the lesion. Small but reactive pupils imply either a metabolic or diencephalic lesion. A fixed, dilated pupil can be seen with expanding supratentorial lesions involving the uncus and the ipsilateral third nerve. Midsize unresponsive pupils imply a midbrain lesion, whereas widely dilated, completely unresponsive pupils suggest brainstem pathology.

Induced eye movements such as the doll's eye (oculocephalic) reflex and cold water caloric testing (oculovestibular, responses) may be useful. A normal response to the doll's eye maneuver is conjugate deviation of the eyes opposite to the direction in which the head is turned. This test is strictly prohibited in any patient with possible cervical spine injury. When testing the oculovestibular reflex in an unconscious individual with an intact brainstem, the fast component is absent, and the eyes move toward the side irrigated with cold water and then remain tonically deviated for 1 minute or longer. The response to the doll's eye maneuver and caloric testing are initially brisk for most causes of metabolic coma but become more difficult to elicit as coma deepens.

Two types of reflex posturing may be elicited by painful stimuli. Decorticate posturing (arm flexion and lower leg extension) occurs with injury to the cerebral hemispheres but intact brainstem function. Decerebrate posturing (internal rotation and extension of the arms with lower leg extension) occurs with damage to the midbrain and pons at the level of the brainstem, implying brainstem dysfunction and therefore a worse prognosis. Flaccidity (no response) is seen with generalized central nervous system (CNS) depression or with compression of the medulla, which indicates a grave prognosis (1,5).

CRITICAL INTERVENTIONS

Initial management of a patient begins with assessment, stabilization, and control of the ABCs, providing supplemental oxygen and ventilation support as needed. Obtain bedside glucose determination with intravenous (IV) access. Focused laboratory testing may include additional studies, including a complete blood count, electrolytes, calcium, renal, liver function tests, blood gas, and a serum ammonia level. Blood and urine cultures of the blood and urine should be sent if there is concern for infection. The child should have continuous cardiopulmonary and oximetry monitoring. An electrocardiogram (ECG) is recommended in cases of dysrhythmia and selected poisonings. A trial dose of naloxone (0.1 mg/kg) should be administered, particularly if the pupils are miotic.

Signs and symptoms of herniation or increased ICP warrant immediate intubation and mild hyperventilation, IV mannitol (0.25 to 0.5 g/kg), and potentially 3% saline may be helpful, but the overriding concern must be the perfusion status and avoiding hypotension (see Chapter 246). Children with focal deficits, evidence of herniation, or increased ICP, and suspected head injury require imaging with head computed tomography (CT). Lumbar puncture is indicated in patients suspected of meningitis if patient is clinically stable enough for the procedure. Consider the use of IV hypertonic saline for patients with AMS and diabetic ketoacidosis with cerebral edema (14,15) (see Chapter 274).

Further management and treatment options are based on the history, signs, symptoms, and physical findings. Therapeutic options include administration of broad-spectrum antibiotics for patients with suspected infection, antidote therapy for suspected poisonings, antiepileptic medications for seizures, and correction of fluid, electrolyte, or acid–base abnormalities. Young children can quickly become hypothermic when exposed to the ambient temperatures in the ED. External or overhead warming devices are strongly recommended to prevent hypothermia (1,4,16).

DISPOSITION

Final disposition is dependent on the suspected diagnosis and the child's condition. Generally, a child with AMS warrants further inpatient evaluation in an intensive care unit. Ongoing reevaluation, reassessment, and modification of therapy are essential until transfer can be accomplished.

Common Pitfalls

- Failure to adequately assess and aggressively manage the ABCs.
- Failure to obtain a rapid bedside glucose or to consider an electrolyte disturbance.
- Failure to consider diagnoses that may present as AMS in children: Atypical or subtle seizures (no tonic–clonic activity), intussusception, ingestions, and child abuse (17).
- Failure to reassess and modify therapy as needed.

CHAPTER 238

Ataxia

Peter S. Auerbach and Jennifer C. Huffman

Acute ataxia is an uncommon and distressing emergency department (ED) complain, but in a previously healthy child is generally due to a benign process and carries an excellent prognosis for full recovery. Emergency physicians must nevertheless remain aware of the rare life-threatening causes of ataxia.

Ataxia refers to any disturbance in the coordination of movement and can be the result of dysfunction at virtually any level of the nervous system. Moreover any general metabolic disturbance of the central nervous system (CNS), such as hypoglycemia or drug or toxin exposure, can also cause ataxia (1).

Ataxia can be divided into categories based on the neurologic structure involved: (1) cerebellar (the most common), (2) sensory, (3) vestibular, and (4) motor. Cerebellar ataxia typically manifests as a wide-based staggering gait, abnormal gross motor movements, or swaying of the trunk or head while at rest. In contrast, sensory ataxia is associated with a cautious high-stepping gait (exaggerated elevation of the feet, which are then brought down suddenly in a flopping manner), an abnormal Romberg sign (loss of balance with the eyes closed), problems with fine motor movements, and loss of position and vibratory sensation. Vestibular ataxia presents with vertigo, nausea, and nystagmus. Motor ataxia (sometimes called *pseudoataxia*) results from muscle weakness rather than a loss of coordination, and may be associated with loss of reflexes and tone, as in Guillain–Barre Syndrome (GBS).

Ataxia can also be classified into acute, episodic or recurrent, and chronic causes. *Acute* ataxia, defined as ataxia present for <72

hours in a previously healthy child, is of primary concern to the emergency physician. Episodic and chronic ataxias are usually associated with other CNS abnormalities, or with genetic or metabolic disorders. *Acute ataxia is generally benign, and requires no treatment once serious conditions such as posterior fossa tumor, encephalitis, or demyelinating diseases, including GBS, have been ruled out.*

CLINICAL PRESENTATION

Most previously well children with acute ataxia are brought to the ED for an unsteady gait or refusal to walk. Other less common complaints include difficulty in reaching for toys, abnormal eye movements, or a change in speech. The two most common causes of acute ataxia in children are acute postinfectious cerebellar ataxia (APCA; also known as acute cerebellar ataxia) and drug ingestions. Features indicating a more serious cause of ataxia, such as encephalitis or a mass lesion, include acute changes in mental status, behavior or personality change, headache, vomiting, fever or meningismus, and diplopia. Other important historical features include recent head injury, seizures, a loss of developmental milestones, or a family history of neurologic disorders.

Physical examination should focus on ruling out potentially life-threatening causes of ataxia such as mass lesion, infection, or trauma. Patients must be carefully examined for subtle focal neurologic deficits, as well as papilledema, which may indicate a mass lesion. Changes in mental status, signs of trauma, fever, and meningismus are clues to either trauma or acute infection. A toxicologic cause of ataxia may be suggested by manifestations of a specific toxidrome (e.g., anticholinergic), an altered level of consciousness, or nystagmus. Children with APCA should have a normal mental status and general physical examination aside from their ataxia, including normal vital signs (2).

The neurologic examination may be very challenging in a young child. Coordination testing must focus on a careful observation of gait, truncal position and stability, ability to reach for toys and

manipulate objects, and eye movements. Assessment of speech is important in older children, specifically to detect the scanning type of dysarthria which can occur with cerebellar dysfunction (characterized by abnormal variation in volume and separation of syllables) (Table 238.1).

TABLE 238.1

Signs of head/neck trauma

DIFFERENTIAL DIAGNOSIS

Acute ataxia in a previously healthy child is almost always caused by a limited number of etiologies (Table 238.2). More than 60% of children with acute ataxia have either APCA or a drug ingestion (3). GBS and acute disseminated encephalomyelitis (ADEM) account for a smaller proportion of cases. Table 238.3 lists a number of rare but serious causes of acute ataxia that should not be missed in the ED, but these conditions almost never present with isolated ataxia in an otherwise well child.

TABLE 238.2
Common Causes of Acute Ataxia in Children

Acute postinfectious cerebellar ataxia
Drug ingestion
Demyelinating disease (e.g., Guillain–Barré syndrome, ADEM)

TABLE 238.3
Life-Threatening Causes of Acute Ataxia in Children

Hypoglycemia
Drug overdose
Cerebellitis/encephalitis
Meningitis
Intracranial mass lesion
Hydrocephalus
Intracranial bleed
Vertebrobasilar dissection
Stroke
Vasculitis
Paraneoplastic syndrome (e.g., opsoclonus–myoclonus syndrome from neuroblastoma)

APCA, accounting for more than one-third of cases of acute ataxia cases in children, is thought to result from cerebellar demyelination following an antecedent illness, either as an autoimmune phenomenon or from direct infection (3). It is seen most commonly in children younger than 6 years and is most often been linked to varicella infection (4,5). It has also been reported in association with Epstein–Barr virus, enterovirus, herpes viruses, influenza A and B, hepatitis A, as well as with viral upper respiratory tract infection and some bacterial infections. The symptoms appear suddenly 1 to 3 weeks after an illness, are maximal at onset, and include dramatic truncal ataxia and gait instability. Most children recover completely within 3 months without treatment (6). APCA is not associated with fever, seizures, altered mental status, or focal neurologic deficits, and *the presence of any of these factors makes the diagnosis highly unlikely.*

Drug ingestion and toxin exposure should figure prominently in the differential diagnosis, even if not initially reported (3). Young children often present with ataxia caused by ingestion of anticonvulsants (e.g., phenytoin, phenobarbital, carbamazepine, valproic acid, topiramate), antihistamines, benzodiazepines, dextromethorphan, or alcohol (7). Older children often present after

recreational drug or alcohol use. In both age groups, the ataxia is often accompanied by mental status changes. Because the history may not be readily forthcoming and because drug ingestions are not uncommon in children, the physician should have a low threshold for ordering a toxicology screen.

Guillain–Barré syndrome, an acute ascending inflammatory demyelinating polyneuropathy, presents with ataxia in up to 15% of pediatric cases (8). Because this syndrome affects the peripheral nerves and typically spreads from distal to proximal, the extremities are generally more affected than the trunk. As with APCA, Guillain–Barré syndrome is usually a postinfectious, autoimmune phenomenon; the key to diagnosis is extremity ataxia combined with areflexia or hyporeflexia early in the course of the disease. The Miller–Fisher variant of Guillain–Barré syndrome is characterized by the triad of ataxia, areflexia, ophthalmoplegia, and other cranial nerve abnormalities. In contrast to APCA, Guillain–Barré syndrome requires hospitalization since it may progress to respiratory failure. Treatment options include intravenous immunoglobulin (IVIG) and plasmapheresis, although most patients recover completely without treatment (9). Other less common postinfectious neurologic syndromes may also present with ataxia, including ADEM and transverse myelitis, both of which are often treated with high-dose steroids (10).

Acute cerebellitis is a localized form of acute encephalitis that is potentially life-threatening and often associated with a poor outcome (11). Although both APCA and cerebellitis are infectious or postinfectious in etiology, cerebellitis presents with variable degrees of altered mental status (ranging from mild somnolence to coma), headache, irritability, and vomiting; neuroimaging is abnormal, with findings ranging from localized cerebellar edema to compression of the fourth ventricle, acute hydrocephalus, and tonsillar herniation (12).

Another serious cause of acute ataxia is intracranial mass lesion. More than half of primary brain tumors in children are located in the brainstem or cerebellum, and can produce ataxia by a direct mass effect or as a result of hydrocephalus. A history of progressive

ataxia is usually elicited, along with headache, visual changes, morning vomiting, and personality changes. The physical examination may reveal papilledema or focal neurologic deficits. Metastatic lesions can affect the cerebellum as well, and occult distant malignancies can present with ataxia in association with opsoclonus (rapid, chaotic eye movements) and myoclonus (rapid, chaotic contractions of individual muscles or muscle groups). Opsoclonus–myoclonus syndrome occurs most commonly in children between the ages of 6 months and 3 years and is the result of a cerebellar paraneoplastic autoimmune response; it is seen in more than half of cases of neuroblastoma (13).

Head injuries can lead to ataxia because of intracranial hemorrhage, mass effect, or cerebellar contusion. Postconcussive syndrome may also cause ataxia, but this is a diagnosis of exclusion. Neck injuries can cause vertebrobasilar artery dissection, with cerebellar and brainstem ischemia or infarction. Cerebellar strokes, though rare in children, can result from bleeding disorders, arteriovenous malformations, or CNS vasculitis (e.g., Kawasaki disease).

Less serious causes of ataxia include childhood migraine variants, epilepsy, conversion disorder, labyrinthitis, and myositis. Basilar migraine and benign paroxysmal vertigo (BPV) may explain most forms of episodic or recurrent ataxia in children or adolescents (14). Epilepsy infrequently manifests as ataxia, usually in association with some degree of altered consciousness (e.g., complex partial seizures). More commonly, patients with known epilepsy are ataxic as a side effect of their seizure medications. Conversion disorder is a diagnosis of exclusion but can usually be identified by characteristic features (e.g., complex lurching movements that require a high degree of coordination; absence of a wide-based stance; or variable and inconsistent physical examination findings, especially when the patient is unaware of being observed) in the face of an otherwise normal neurologic examination.

ED EVALUATION

Keeping in mind that most cases of acute ataxia in otherwise healthy children are caused by either APCA or drug ingestion, the primary goal of the ED evaluation is to eliminate the possibility of a more serious etiology. The first and most important step is a thorough history and physical examination, which together can help eliminate the vast majority of life-threatening causes.

In the absence of other findings, a comprehensive toxicology screen may be a useful laboratory test, even when an ingestion is unsuspected by history. A limited “drugs of abuse” screen will miss the majority of ingestions in younger children. Routine laboratory studies, such as electrolytes and a complete blood count, are of very low yield (3). But in children taking antiepileptic drugs, as well as in those with family members taking such medications, drug levels should be checked.

Lumbar puncture is of low utility in cases consistent with APCA or drug ingestion, and in well-appearing, mildly symptomatic patients. However, it is particularly important in patients with altered mental status or fever. If performed due to altered mental status, an opening pressure should be measured because initial cerebrospinal fluid (CSF) analysis may be normal in cases of cerebellitis and with other serious CNS infections. An elevated CSF cell count suggests meningitis or encephalitis, and an elevated protein in combination with a normal cell count (cytoalbuminologic dissociation) is supportive of Guillain–Barré syndrome or other demyelinating diseases.

Neuroimaging should be performed if a mass lesion, hydrocephalus, elevated ICP, or trauma is suspected. Although CT is more readily available than MRI, it is of limited value in visualizing the posterior fossa and brainstem. If a mass lesion is strongly suspected, an MRI must be obtained (though not necessarily on an emergent basis) despite a normal CT. MRI may show other abnormalities missed by CT, such as findings indicative of acute cerebellitis, stroke, or demyelinating disease.

Electroencephalography (EEG) may be helpful if epilepsy is suspected by history, and consultation with a neurologist should be considered.

KEY TESTING

- Comprehensive toxicology screen
- Lumbar puncture if patient has altered mental status
- MRI or CT of the head, depending on availability

ED MANAGEMENT

Treatment is typically focused initially on identifiable causes of ataxia such as hypoglycemia, encephalitis, meningitis, elevated ICP, and drug overdose. Most children with APCA recover completely within 3 months, there is no specific treatment, and hospitalization is often unnecessary (2). Children with drug ingestions are managed according to the specific drug(s) involved, but a social service or Children's Protective Services (CPS) referral should be made depending upon the circumstances.

Guillain–Barré and other demyelinating neurologic syndromes (e.g., ADEM) may require emergent airway management if severe and require admission in all cases. Early consultation with a neurologist is essential. Other causes of ataxia, such as tumors and CNS infection, generally require admission.

CRITICAL INTERVENTIONS

- Rule out life-threatening etiologies of ataxia.
- Reassure parents of the benign and self-limited nature of most causes of acute ataxia in childhood.

DISPOSITION

Children who are mildly symptomatic, appear well, and have a history and physical examination consistent with APCA may require no further ED evaluation and can be discharged home if close follow-up can be assured. Parents should be counseled on injury prevention, as children with APCA are at increased risk of injury until recovery is complete. If the diagnosis is in doubt, further testing should be done to rule out other diagnostic possibilities.

Most other causes of acute ataxia require admission for treatment or further evaluation, including consultation with appropriate specialty services. In the case of minor ingestions, discharge from the ED should be considered if the home environment and social situation are judged to be safe.

Common Pitfalls

- Failure to do a thorough history and physical examination before ordering extensive laboratory tests or neuroimaging.
- Failure to obtain a comprehensive toxicology screen, even in the absence of a history of ingestion.
- Failure to admit an ataxic patient when the diagnosis is in doubt or when prompt outpatient follow-up cannot be assured.
- Failure to counsel on injury prevention if the patient is being discharged.

CHAPTER 239 Pediatric Headache

Wendalyn Little, M. Scott Perry, and Harold K. Simon

Headache is a common emergency department (ED) complaint among children. The majority are found to have headache secondary to minor infectious illnesses or primary headaches such as tension-type or migraine. The complaint of headache in a child or adolescent can be worrisome for patients and caretakers fearing the child has a serious or life-threatening medical condition. There exists a misperception among laypeople that "kids do not get headaches"; however, epidemiologic studies report an incidence of pediatric headache ranging from 3% during the preschool years to over 75% by late adolescence (1–3). Chronic or recurrent headaches in children and adolescents may cause significant school, family, and social disruption. While serious neurologic conditions are rare in pediatric patients, medical providers must remain vigilant and not assign a benign etiology to all pediatric headaches. A careful history and physical examination alone often leads to the correct diagnosis; neuroimaging and laboratory studies are indicated in only a small minority of patients.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Headaches are classified as either primary or secondary. Primary headaches include predominantly tension-type or migraine headache. Secondary headaches are the result of a variety of conditions ranging from benign, self-limited viral illnesses to life-threatening infections or mass lesions. The emergency physician should endeavor to distinguish primary from secondary headache to ensure appropriate

treatment, evaluation and follow-up for secondary headache, and provide a plan for acute symptom relief in the case of primary headache. Providers must also provide reassurance and guidance for patients and families on types of headaches, management of symptoms, and recognition of changing patterns of pain or other worrisome symptoms that should prompt further evaluation.

As in adult patients (see Chapter 12), headache may be further categorized by pattern as acute, acute recurrent, chronic progressive, or chronic recurrent. The differential diagnosis of pediatric headache is quite broad, Table 239.1 lists some common causes, but is by no means an all-inclusive list; a careful history and physical examination are crucial for every patient. Establishing this pattern helps guide an appropriate differential diagnosis (Table 239.1) (4,5). Acute onset headache may be the initial presentation of primary headache disorders, but is more often secondary to an underlying medical condition. The differential diagnosis for this group is broad, including everything from mild viral illnesses to life-threatening infections or other central nervous system etiologies. A careful history and physical examination can generally differentiate between minor and major illness; worrisome features of serious pathology include severe or incapacitating pain, altered mental status, and focal neurologic deficits, such as a new onset cranial nerve dysfunction. Patients with a history of shunted hydrocephalus require special mention, as headache is a common presenting symptom of shunt malfunction and usually requires further investigation in this population.

TABLE 239.1
Common Differential Diagnosis of Headache in the Pediatric Patient

Acute Headache	Recurrent Headache	Chronic Progressive Headache	Chronic Recurrent Headache
Viral respiratory infection	Tension headache	Intracranial tumor	Tension headache
Group A streptococcal pharyngitis	Migraine headache	Idiopathic intracranial hypertension	Migraine headache
Viral meningitis		Intracranial abscess	Analgesic rebound
Bacterial meningitis			
Acute trauma			
Dental caries or abscess			
Toxic exposure			
Ventricular shunt dysfunction			

Acute, recurrent headache describes a pattern of headaches that recur periodically with the same intensity and characteristics. This pattern is most suggestive of a primary headache disorder. The diagnosis of migraine in children rests primarily upon the modified clinical criteria set forth by the International Headache Society in 2004 (6). Migraine may affect even young children, although their inability to completely describe symptoms makes it more difficult to diagnose. Migraine may be frontal or bilateral in children, as opposed to the classic unilateral presentation often described in adults. The pain is described as throbbing, pulsatile, and often incapacitating, in contrast to the dull, annoying nature of tension-type headache pain. The pain of migraine is typically located in the region of the eyes, forehead, and temple and may last from <1 hour to several days. There is often associated nausea or vomiting, and pain is preceded by an aura in some patients. Light, noise, and movement usually aggravate the pain, and a period of sleep frequently results in resolution of symptoms (1,3,4).

Chronic progressive headaches, those increasing in frequency or severity over time, are more concerning for serious intracranial pathology. Associated symptoms such as visual disturbances, weight loss, early morning vomiting, headaches that awaken the child from sleep, and changes in personality, behavior, or school performance should prompt heightened concern for intracranial lesions. However, idiopathic intracranial hypertension (IIH) is another important cause of chronic, progressive headache that deserves consideration. Risk factors for IIH include obesity, female gender, use of certain

antibiotics (e.g., tetracyclines), hypervitaminosis, and oral contraceptive use. Patients may report worsening of headache with Valsalva maneuver, changes in visual acuity, transient visual obscurations, or pulsatile tinnitus. Early recognition is vital given that untreated IIH, can result in optic nerve damage and potentially permanent visual loss (4,7).

Chronic, recurrent headaches are most suspicious for tension-type headache and may be associated with poor sleep habits, obstructive sleep apnea, lack of adequate exercise, poor nutritional habits, or depression. A careful history can often accurately demonstrate these contributing elements. These headaches are typically dull and annoying in character, occur toward the end of the day, and are often relieved with a period of rest. Unfortunately, tension-type headaches are often treated with regular use of analgesic medications, instead of addressing underlying sources of tension or stress. As a result, many patients risk developing analgesic rebound headache.

Analgesic rebound headache has been well described in adults and is widely recognized in children of all ages, especially those who use analgesics more than three times per week. This entity generally presents as frequent, uniform headache, often occurring in the afternoon or evening, and lacking association with other worrisome symptoms (1,4,5,8). These headaches often respond temporarily to analgesics, but the pain will typically return as the medication wears off. Limiting analgesic use is the first step in treatment. Patients also should be counseled on the importance of regular dietary and sleep habits in preventing headache recurrence. Poor sleep habits are a common cause of recurrent headache in children and adolescents. Families should be counseled on the importance of good sleep hygiene, including removal of television, video games, and portable electronic devices from the sleeping area. Enforcing regular mealtimes, encouraging physical activity, and normalizing school attendance and other routines are other lifestyle interventions that may improve these headaches (Table 239.1) (1,4,5,8).

ED EVALUATION

Patients presenting to the ED with headache are frequently seeking pain relief as well as an explanation for concerning symptoms. A complete history and physical examination is of utmost importance and often informs the diagnosis as well as suggesting a management plan.

All patients seen in the ED with a complaint of headache should have a complete set of vital signs, including temperature and blood pressure. Blood pressure in pediatric patients must be interpreted using age-based normal values. While elevated blood pressure itself rarely causes headache, with the exception of hypertensive encephalopathy, persistently elevated blood pressure is concerning for increased intracranial pressure or other pathologic process.

The best assessment of central nervous system "well-being," reflecting cerebral perfusion, oxygenation and overall function, is the patient's level of consciousness. In the pediatric patient, mental status must be judged with regard for the patient's age, developmental level, and usual baseline functioning. Young children may be frightened and uncooperative with an unknown examiner, but should be consolable and interactive with parents or other known caregivers. Older children and adolescents should be appropriately interactive with the treatment team. A full neurologic examination is fundamental and should include evaluation of cranial nerves, motor function, gait, sensation, and deep tendon reflexes. Special care must be taken when approaching the sleeping child, especially during nap or nighttime sleep. While children may be sound sleepers and difficult to awaken, it is imperative that examiners awaken the child enough to obtain an accurate assessment of the child's mental status, including appropriate ambulation.

The head, ears, eyes, nose, and throat should be carefully examined for any signs of trauma or for minor infections such as pharyngitis, otitis media, or upper respiratory infection, all of which are common causes of acute headache. The teeth and gums should be checked carefully for caries or abscess. Fundoscopic examination should be attempted on every patient with headache of unclear etiology. In cases of suspected increased intracranial pressure, pharmacologic dilation and ophthalmology consultation may be

necessary to visualize the fundus adequately and evaluate for papilledema. The patient presenting with fever and headache should be routinely examined for neck stiffness indicative of meningeal inflammation. Finally, the skin and musculoskeletal examination should include inspection for petechiae or purpura, especially in the febrile or ill-appearing patient.

Laboratory evaluation is not routinely indicated in pediatric headache patients, but should be guided by the clinical history and physical examination. Potentially useful tests include rapid streptococcal throat screen or culture, toxicology assay in patients with altered consciousness, co-oximetry in cases of suspected carbon monoxide exposure, and pregnancy testing in adolescent females. Lumbar puncture (LP) should be performed in any patient with fever and neck stiffness or altered mental status, suspicion of subarachnoid hemorrhage, or in patients with persistent headaches and ophthalmologic findings suggestive of IIH. When LP is performed, cerebrospinal fluid (CSF) should be sent for culture, cell count, protein, and glucose. Other studies (cytology, viral testing) may be pursued as clinically indicated. In cases of suspected IIH it is important to obtain a CSF opening pressure. Patients with immunocompromise secondary to malignancy, sickle cell disease, transplant, or HIV infection are at elevated risk of meningitis and specialized laboratory testing should be considered when these patients present with fever and headache.

Neuroimaging, as with laboratory studies, must be guided by historical features and clinical findings. Most children with acute or recurrent headache and a normal neurologic examination do not require emergent neuroimaging. Computed tomography (CT) scan should be considered in patients with altered mental status or focal neurologic deficits, head trauma with severe or worsening headache, or paroxysmal onset of excruciating headache (worrisome for subarachnoid hemorrhage, a relatively rare cause of pediatric headache), and in those with known or potential coagulation abnormalities or with shunted hydrocephalus. Controversy exists as to the necessity of performing CT scanning before undertaking LP because of the theoretical risk of causing cerebral herniation in

patients with space-occupying intracranial lesions. In cases of suspected subarachnoid hemorrhage or IIH, it is probably prudent to obtain imaging prior to LP. In cases of suspected meningitis, if the patient is alert and has a nonfocal neurologic examination, LP may be safe to perform, but should be delayed (without delaying the administration of empiric antibiotics, however) in patients with altered mental status, hemodynamic instability or focal neurologic findings (9,10).

Magnetic resonance imaging (MRI) should be considered in patients with recurrent morning headaches, chronic progressive headache, focal neurologic findings such as cranial nerve deficits, balance or gait abnormalities, persistent head tilt in a young child, and headache associated with personality changes or a decline in school function. MRI allows for better imaging of the posterior cranial fossa, a common site of mass lesions in children (1,3,9). MRI also avoids the radiation exposure associated with CT imaging.

KEY TESTING

- All testing should be guided by history and physical examination
- Emergent neuroimaging should be obtained in patients with altered mental status, concern for intracranial hemorrhage or mass lesion, patients with coagulopathy or bleeding disorders, patients with shunted hydrocephalus, or when concern exists for increased intracranial pressure
- laboratory testing might include pregnancy testing, toxicology screening (including co-oximetry measurement), and evaluation of cerebrospinal fluid for infection
- MRI is preferred over CT imaging for evaluation of the posterior cranial fossa

ED MANAGEMENT

Treatment of the pediatric headache patient is based on presumptive diagnosis. Many acute headaches are caused by minor viral or bacterial infections such as streptococcal pharyngitis. Once more serious causes are excluded, these headaches are often adequately

treated with short courses of over-the-counter analgesics such as ibuprofen or acetaminophen. Tension-type or migraine headaches may also respond to acetaminophen or ibuprofen in appropriate weight-based doses, especially if given early in the headache attack.

For migraine headaches, an abundance of treatment regimens have been proposed and investigated yet none have proven completely efficacious, making firm recommendations difficult. Among these are ketorolac, magnesium, antihistamines, valproic acid, and centrally acting dopamine agonists such as metoclopromide. In addition, intravenous hydration and supplemental oxygen are used by some providers. The 5HT1 agonists or “triptans” are another group of medications used to treat migraine, but their use has not been proven to be superior to other regimens in studies of adult or pediatric migraine. Antiemetics are also an important consideration, as the nausea and emesis associated with migraine can be debilitating for many patients. Narcotics should be used sparingly, if ever, in cases of migraine as they may lead to rebound pain, have the potential to be habit-forming, and may have an unfavorable side-effect profile. Important adjuncts to pharmacologic treatment include providing a dark, quiet room to minimize stimulation and promote sleep, which may abort or shorten the migraine attack (1,4,5,11–14).

A migraine lasting more than 72 hours may be considered status migrainosus and often requires consultation with a pediatric neurologist. Proposed treatment protocols include combinations of antiemetics, sedatives, steroids, ergotamines, or analgesics, but there are no rigorous studies to support the use of any particular treatment regimen (11–14).

In cases of suspected IIH, LP may be both diagnostic and therapeutic. It is important that opening pressure be measured in all cases of suspected IIH. Consideration should be given to draining a larger than normal volume of CSF during the procedure and obtaining a closing pressure measurement at the end of the procedure to demonstrate a decrease in CSF pressure.

Patients discharged from the ED should be encouraged to seek medical attention if the headache worsens, changes in character, or

persists for more than 2 to 3 days. They should be encouraged to see their primary care provider to ensure proper follow-up.

CRITICAL INTERVENTIONS

- A thorough history, full set of vital signs (including blood pressure), and physical examination should be performed on all patients presenting with headache.
- Emergent neuroimaging and laboratory analysis should be considered for patients presenting with headache accompanied by altered mental status or an abnormal neurologic examination.
- In cases of suspected meningitis, empiric antibiotic coverage should be provided if LP is delayed for the purpose of obtaining imaging or stabilizing an ill-appearing patient.
- LP may be both diagnostic and therapeutic in cases of suspected IIH. Imaging before LP should be considered on a case-by-case basis.

DISPOSITION

ED disposition of pediatric patients with headache is dependent on the presumed underlying cause of the headache. Patients with life-threatening causes such as meningitis, intracranial hemorrhage or mass lesion, or ventricular shunt malfunction should have appropriate subspecialty consultation and admission to the hospital for further evaluation and treatment. Patients with IIH can potentially be discharged if headache improves after LP and if close neurology and ophthalmology follow-up can be ensured, but they may require admission for medical management, repeat therapeutic LP, or consideration of surgical procedures to decrease intracranial pressure and preserve vision. Patients with minor infections may be discharged with appropriate follow-up instructions and treatment, if indicated, for the underlying infection as well as instructions for safe use of over-the-counter analgesic medications.

Patients with migraine or tension-type headache may be discharged after treatment if they have experienced sufficient relief of pain, are able to tolerate oral intake without vomiting, and

maintain normal vital signs and mental status. These patients should be counseled on early use of analgesics with headache attacks, but warned of the danger of rebound headache in cases of analgesic overuse. Patients with severe migraine refractory to standard ED management may require hospitalization for subspecialty consultation and pain management.

Patients with chronic or recurrent headaches resistant to common analgesics may benefit from referral to a neurologist for evaluation and consideration of prophylactic treatment. Patients with chronic or recurrent headaches interfering with school or social functioning may also benefit from a multidisciplinary pain management service where they may receive not only medication but counseling and support services, as these headaches are often associated with social or behavioral comorbidities.

Common Pitfalls

- Inappropriately assuming a child is just sleepy because it is nap time or late at night. Subtle signs of altered mental status can be easy to miss during the overnight hours.
- Pursuing CT scanning or extensive laboratory analysis on a pediatric headache patient because of the misperception that "kids do not get headaches."
- Failure to recognize that recurrent headaches awakening a child from sleep, occurring upon morning awakening, or associated with personality changes, gait disturbance or head tilt may be signs of increased intracranial pressure or an intracranial mass lesion, especially in young children.

CHAPTER 240
Oral Lesions

Therese L. Canares and Dale Steele

Pediatric oral lesions are primarily the result of infectious etiologies including herpes, Coxsackie and group A *Streptococcus* (GAS), among others. Complaints of oral bleeding may arise from post-tonsillectomy eschar. Autoimmune causes of oral lesions in children include Kawasaki disease (KD) and Stevens–Johnson syndrome (SJS).

CLINICAL PRESENTATION

Herpes simplex virus (HSV) causes primary herpetic gingivostomatitis and is characterized by fever, gingivitis, and a vesicular rash that leaves shallow, painful ulcers (Fig. 240.1).

FIGURE 240.1 Infant with herpetic gingivostomatitis. An infant with a healing vesicle on the upper lip and a shallow ulcer in the buccal mucosa. Vesicles are seen in the anterior oral mucosa, periorally or, particularly in a thumb-sucking child in the periungual area (i.e., herpetic whitlow).

Coxsackievirus causes herpangina, a summertime condition characterized by small, tender vesicles with an erythematous halo that may be similar to herpes gingivostomatitis, however appear primarily in the posterior pharynx. Coxsackievirus is also the infectious etiology associated with hand-foot-and-mouth disease (Fig. 240.2).

FIGURE 240.2 Hand, foot and mouth disease: This is caused by coxsackie virus, and manifests as herpangina, with fever, and a

papulovesicular rash in the palms, soles or buttocks.

Infectious mononucleosis and GAS pharyngitis both present with exudative pharyngitis, palatal petechiae, cervical lymphadenopathy, and fever. GAS pharyngitis patients commonly complain of fever and sore throat without a cough. Mononucleosis is distinguished by profound fatigue and posterior cervical lymphadenopathy. Oral candidiasis causes a white, friable pseudomembrane, frequently seen in infants or immunosuppressed patients. The clinician should evaluate for erythematous satellite papules of candidal diaper dermatitis. Measles is a clinical diagnosis based on whitish-blue papules on an erythematous base in the buccal mucosa (Koplik spots), and associated cough, coryza, conjunctivitis, and rash. As declining vaccination rates threaten herd immunity, measles outbreaks in the United States are reaching their highest rates since 1996 and are increasingly relevant for the emergency clinician (1).

Surgical consultation is occasionally needed for intraoral emergencies. Delayed post-tonsillectomy hemorrhage is uncommon (1% to 5%) but potentially life-threatening and should be thoroughly evaluated (Fig. 240.3) (2).

Many autoimmune conditions have associated oral findings, however the clinician must be diligent to identify high-acuity conditions such as KD and SJS. Oral lesions of KD may include cracked red lips, strawberry tongue, crusting of the lips and mouth, or a nonexudative pharyngitis. Similarly to KD, SJS causes severe mucositis with painful erosions, crusting, and sloughing of mucous membranes (Fig. 240.4).

FIGURE 240.3 Post-operative tonsillectomy eschar and hemorrhage: During healing, a whitish-yellow fibrin clot or eschar (left) develops in the tonsillar fossae, which may be confused as exudate or thrush. The eschar sloughs from underlying granulomatous tissue 7-10 days post-operatively, which may cause bloody sputum, hematemesis, or hemodynamic instability. Clot is visible in the right tonsillar pillar.

FIGURE 240.4 Oral findings in Stevens–Johnson syndrome. A 9-year-old with ulcerated, crusted, macerated lips.

DIFFERENTIAL DIAGNOSIS

Beyond the aforementioned pathologic conditions, a number of benign oral lesions may be seen in the ED. These include aphthous ulcers, geographic tongue, angular cheilitis, gum boil, ranula, Bohn nodules, Epstein pearls, mucocele, papillomas, fibromas, hemangiomas, pyogenic granulomas, lichen planus, and dental eruption cysts.

ED EVALUATION

Oral lesions can often be diagnosed clinically. Confirmation of HSV is made by viral culture, polymerase chain reaction, or immunofluorescence staining (DFA) on cells scraped from the base of unroofed vesicles (3). GAS pharyngitis is diagnosed by rapid antigen testing and confirmatory culture (4). Mononucleosis frequently causes an atypical lymphocytosis on complete blood count (CBC). To better characterize the diagnosis of mononucleosis EBV serology should be performed, since the heterophile antibody (Monospot) test

has poor sensitivity in children. Heterophile antibodies are positive in only 25% to 50% of children under 12 years of age (5). A CBC and type and screen should be obtained on those with post-tonsillectomy hemorrhage. Autoimmune disorders show nonspecific elevation of acute-phase reactants. Patients with concern for KD should have CBC, chemistry, urinalysis, and liver function tests to evaluate for anemia, sterile pyuria, and transaminitis (6).

KEY TESTING

- CBC with type and cross for post-tonsillectomy hemorrhage
- Serum electrolytes in dehydrated children with oral lesions and limited PO intake

ED MANAGEMENT

Management of oral lesions consists of supportive care and treatment of the underlying disease (Table 240.1). Assessment of dehydration and pain control are absolutely essential and may justify inpatient admission. Painful oral lesions are initially approached with analgesics such as ibuprofen or acetaminophen. “Magic mouthwash” is often used for painful lesions, with care not to overdose diphenhydramine. Avoid toxicity from topical lidocaine by using cotton-tipped applicator in infants, or have the child swish and spit (7). Narcotics are indicated for failure of over-the-counter analgesics or in severe cases. Tolerance of oral fluids must be demonstrated prior to discharge. Inability to tolerate liquids or severely dehydrated patients with tachycardia, dry mucous membranes and decreased urination may require intravenous hydration and perhaps admission. Patients with mononucleosis should be advised to avoid contact sports for at least 3 weeks to reduce the risk of splenic rupture (5). Subspecialty consultation should be made for post-tonsillectomy hemorrhage and potential intraoperative cauterization or for autoimmune conditions that require systemic treatment.

TABLE 240.1
Suggested Therapy for Pediatric Oral Lesions (8)

Condition	Medication	Dose	Route	Freq	Duration	Note
Painful oral lesion or mucositis	"Magic mouthwash" (diphenhydramine + Maalox, +/– viscous lidocaine 2%)	Limit by diphenhydramine 5 mg/kg/d	PO	q6h	As needed	Mix as a 1:1:0.5 ratio If using lidocaine, patient should swish and spit
HSV primary	Acyclovir	40–80 mg/kg/d (max 1 g/24 hr)	PO	q6–8h	5–10 d	For age <12 yrs; start within 3–4 d onset
HSV recurrent	Acyclovir	1 g/d	PO	q4–6h	5 d	In recurrent HSV, may opt for 2.4 g/d, q8h, × 2 d. May use valacyclovir for less frequent dosing
GAS pharyngitis	Benzathine penicillin G	600,000 units (<27 kg) or 1.2 million units (>27 kg)	IM	Once		Medication selection is based on compliance, palatability, and parental preference
	Amoxicillin	25–50 mg/kg/d	PO	q8–12h	10 d	
Oral candidiasis	Nystatin	1 mL to each side of mouth (infants); 4–6 mL (children)	PO	q6h	Until 48–72 hrs postsymptom resolution	Children should swish and swallow. Parent should clean all nipples and pacifiers. May opt for fluconazole
KD	IVIG	2 g/kg	IV		Institution protocol	Initiate within 10 d of symptom onset

CRITICAL INTERVENTIONS

- Assess for dehydration in infants and toddlers with poor oral intake or decreased urine output
- Use topical lidocaine with caution for systemic toxicity (arrhythmias or seizures) (7)
- In post-tonsillectomy bleeds ensure a patent airway, obtain a CBC, T&S, and consult the surgeon
- Treat KD with IVIG within the first 10 days of illness to prevent coronary artery aneurysms (6)

DISPOSITION

Disposition is case dependent. Patients may be discharged home with over-the-counter, or rarely narcotic pain medication. Patients are admitted if unable to tolerate oral intake, there is evidence of sepsis or systemic disease warrants admission.

Common Pitfalls

- Ensure adequate pain control and tolerance of oral liquids prior to discharge.
- Consider child abuse if oral HSV coincides with genitourinary lesions in a prepubertal child.
- Maintain an index of suspicion for KD in children with prolonged fever.
- Consider mononucleosis with splenic rupture in fever, fatigue, tonsillar lesions, and left upper quadrant abdominal pain.

CHAPTER 241
Neck Masses

Bonnie Mackenzie and Siraj Amanullah

Neck masses present frequently in pediatric practice and constitute a wide range of diagnostic possibilities. The ED is often the frontline for diagnosis of congenital cysts and malignancies. A basic understanding of anatomy and embryology can simplify the approach to evaluating nontraumatic neck masses of infectious, inflammatory, or malignant origin. While the vast majority of patients have benign diagnoses related to lymphadenitis, clinicians must always ensure that potential airway problems are addressed in a timely fashion.

CLINICAL PRESENTATION

The head and neck develop from a branchial apparatus which, at the mesodermal level, is comprised of the first through fourth and sixth branchial arches (the fifth arch regresses and is not clinically relevant). The branchial arches, derived structures, and associated congenital cyst types (congenital neck masses) are summarized in Table 241.1.

TABLE 241.1
Branchial Arches, Derived Structures, and Associated Congenital Neck Masses

Arch	Important Nerve	Important Muscles	Important Bones/ Cartilages	Important Soft Tissues	Location of Associated Congenital Cyst Type (Frequency)
First (mandibular)	CN V (trigeminal)	Muscles of mastication	Malleus, incus, mandible	External ear canal	Duplication anomaly of external auditory canal or cyst below angle of mandible (rare)
Second (hyoid)	CN VII (facial)	Muscles of facial expression	Stapes, styloid process, lesser horn of the hyoid	Palatine tonsils	Inferior to angle of the mandible and anterior to sternocleidomastoid (**most common;** 10% bilateral)
Third	CN IX (glossopharyngeal)	Superior constrictor muscles	Greater horn of the hyoid	Internal carotid artery	Deep to the lower third of sternocleidomastoid, often lateral to carotid artery (uncommon)
Fourth and Sixth	CN X branches (vagus): superior laryngeal, recurrent laryngeal	Inferior constrictors, esophageal striated muscles	Thyroid cartilage, cricoid cartilage, arytenoid cartilage, corniculate cartilage, cuneiform cartilage	Aortic arch, right subclavian artery, aorta, thyroid gland, parathyroid glands	Deep to the internal carotid artery, can extend into the thyroid gland (very rare)
Fifth regresses	N/A	N/A	N/A	N/A	N/A

Anatomically, the neck can be divided into an anterior and posterior triangle separated by the sternocleidomastoid muscle. The boundaries of these triangles, and the important contents of each, are outlined in Table 241.2 and Figure 241.1 (2).

TABLE 241.2
Boundaries and Contents of the Anterior and Posterior Triangles of the Neck

Triangle	Boundaries	Contents
Anterior	Midline of the neck, inferior edge of mandible, sternocleidomastoid muscle	Suprahyoid and infrahyoid muscles, mylohyoid, and facial nerve
Posterior	Sternocleidomastoid muscle, anterior border of trapezius muscle, middle third of clavicle	Cutaneous branches of the cervical plexus, CN X (accessory), arterial branches of the thyrocervical branch, lymph nodes, veins

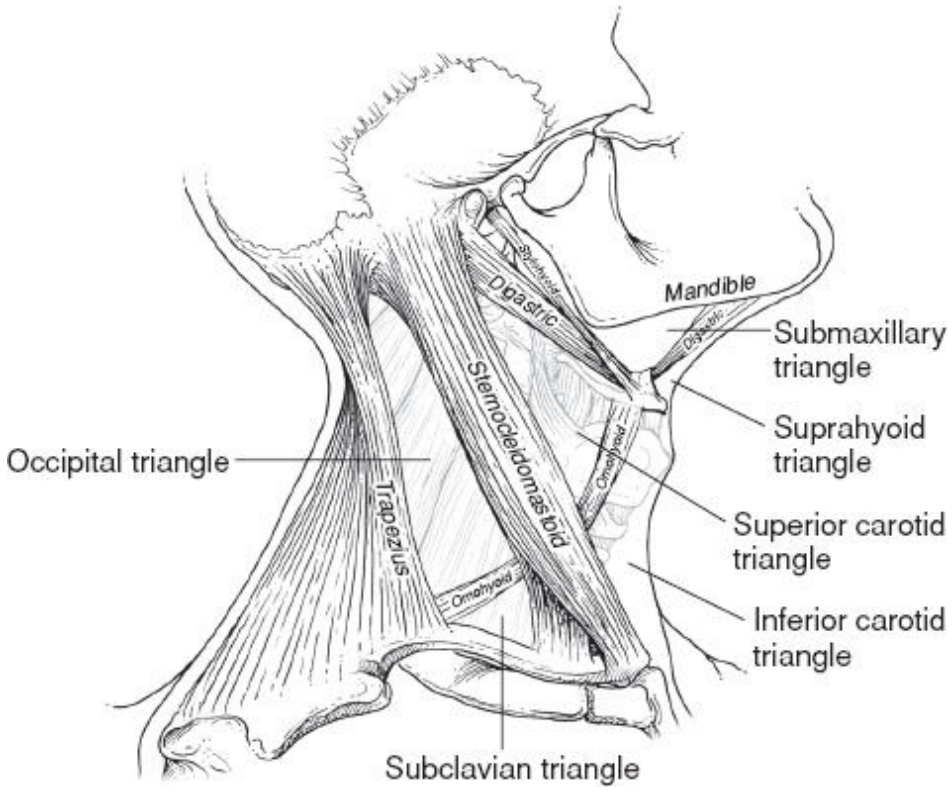

FIGURE 241.1 The anterior and posterior triangles of the neck, lithograph plate from Gray's Anatomy.

The clinical presentation of a neck mass can include diffuse or localized swelling, fever, poor oral intake, neck stiffness, torticollis, drooling, and various other symptoms; see Table 241.3 (3).

TABLE 241.3
Common Presenting Symptoms Associated with Neck Masses

Neck swelling (localized, diffuse)	Globus phenomena (sensations of lump in throat)	Stridor
Fever	Odynophagia	Speech disorders Hoarseness
Erythema	Otalgia	Head tilt/torticollis
Ecchymosis	Muffled, hot potato voice	Respiratory difficulty
Dysphagia	Trismus	Weight loss
Drooling		CN IX–XII palsies

Table 241.4 lists common presentations of neck masses by anatomic location, with likely etiologies and distinguishing clinical features.

TABLE 241.4
Anatomic Neck Mass Presentations

Location	Etiologies	Distinguishing Features
Midline	Thyroid mass/goiter	Tachycardia, weight loss
	Thyroglossal duct cyst	Moves with tongue protrusion
Anterior triangle	Lymphadenopathy	Enlarged, mobile nodes
	Lymphadenitis	Erythema, tender, fever
	Branchial cleft cysts	Often secondarily infected
	Sialadenitis	Parotitis obscures jaw angle
	Laryngocele	Lateral air-filled sac
	AV fistula	Pulsatile, bruit
Posterior triangle	Cystic hygroma	Diffuse edematous swelling
	Lymphadenopathy Lymphadenitis	Consider malignancy if persistent, fever, weight loss
Diffuse swelling or head tilt/ torticollis	Deep neck infections	Fever, sore throat, neck pain
	Fibromatosis colli	Firm mass on sternocleidomastoid in infant

Ill-Appearing Child with Fever

Fever and localized neck swelling that is tender and warm to the touch (with or without skin changes) suggests a superficial or deep neck infection. This may originate from local structures including tonsils, middle ear, lymph or salivary glands, a congenital cyst or, rarely, from a malignancy.

Deep neck infections include peritonsillar abscesses (with possible extension in neck planes), retropharyngeal abscesses (primarily seen in children $\leq$5 years old due to regression of involved lymph nodes with age), parapharyngeal abscesses, sialadenitis, supramylohyoid infections, and superinfected congenital malformations. Congenital malformations can become clinically evident at any point in life, and often present as a result of super-infection (1).

Diagnosing potentially life-threatening infections can be challenging due to the anatomic complexity and the subtle or overlapping presentations of more benign conditions such as cervical lymphadenitis. In addition, relative to adults, pediatric patients have the potential for retropharyngeal or parapharyngeal infections of lymphoid tissue in spaces that generally atrophy by adulthood. Such infections present with neck pain, swelling, or stiffness, associated with sore throat, poor oral intake, drooling, stridor, or lymphadenopathy. Drooling is an especially worrisome marker for airway compromise. In very young infants (<9 months), the most common presenting symptoms of deep neck infections include neck swelling, lymphadenopathy, fever, rhinorrhea, poor oral intake, and cough (3).

Potentially life-threatening complications of deep neck infections include mediastinitis, Ludwig angina, and Lemierre syndrome. Ludwig angina is a rapidly progressive, firm cellulitis of the floor of the mouth usually originating from a diseased tooth, but it may also originate from a peritonsillar or parapharyngeal abscess, epiglottitis, or a penetrating injury to the floor of the mouth. Lemierre syndrome, usually seen in older children, is an infected thrombosis of the internal jugular vein that is associated with parapharyngeal infections such as pharyngitis, tonsillitis, cervical lymphadenitis, and parotitis. Lemierre syndrome should be considered in a sick-appearing child with significant neck pain (3,4).

Neoplasm should be considered in a child with a firm, nonmobile, enlarging neck mass, and a history of fevers, weight loss, bone pain, or night sweats. Other concerning features include a persistently enlarged lymph node that has been present for several weeks, enlarged nodes in the posterior triangle or supraclavicular space, or lymphadenopathy that is associated with recurrent epistaxis, hoarseness, cranial nerve palsies, or otorrhea, which may indicate local tissue invasion by a mass (5,6). A list of benign and malignant head and neck neoplasms is included in the differential diagnosis in Table 241.4.

Well-Appearing Child with Fever

The most likely diagnoses include reactive lymphadenopathy, lymphadenitis due to viral or bacterial pathogens, and salivary gland infections. If fever and adenopathy are persistent (i.e., for more than a few weeks), etiologies to be considered should include mycobacterial infections, granulomatous processes, and *Bartonella henselae* infection (catscratch fever) (6).

Salivary gland infections should be considered as a cause of neck swelling because the majority of the parotid gland tissue is below the angle of the mandible. Parotitis often presents as an acute neck swelling that obscures the angle of the jaw Figure 241.2. In pediatric patients, acute tender enlargement of the parotid gland is usually infectious, or due to salivary duct stones (7). The differential diagnosis of parotitis includes viral infections, including mumps due to paramyxovirus, rarely seen in immunized patients, Coxsackieviruses, CMV, HIV-related EBV infection, *Staphylococcus aureus* infection, *mycobacterium* tuberculosis, juvenile recurrent parotitis (a chronic condition without a well-defined etiology that develops between age 3 and 6 years), and bulimia nervosa sialadenosis (8).

FIGURE 241.2 Parotitis in a toddler. Note how the enlarged parotid gland obscures the angle of the mandible.

Well-Appearing, Afebrile Child

This category includes mostly noninfected congenital lesions and vascular anomalies. Congenital malformations are common in the pediatric population, but may not become evident until adolescence or adulthood; they should therefore be considered in the differential of any patient presenting with a neck mass (1,9,10). The most common include branchial cleft anomalies (cysts being most common), thyroglossal duct cysts, cystic hygromas, laryngoceles, and epidermoid and dermoid cysts (see Chapter 261).

While patients with vascular malformations may not appear toxic, these lesions can potentially cause life-threatening complications due to airway compromise, bleeding, or high-output cardiac failure. Hemangioma, a very common pediatric vascular tumor, may present as a neck mass and cause subglottic obstruction or high-output cardiac failure. Hemangiomas are generally enlarging red or blue masses that typically proliferate before involuting. Cutaneous lesions may indicate the presence of hemangiomas in other organs, and one-half of infants with subglottic hemangiomas also have a cutaneous hemangioma. Any hemangioma found in the "beard distribution" (the preauricular areas, chin, anterior neck, and lower lip) should trigger further evaluation for associated airway hemangiomas (1,11). For children without stridor or drooling, this evaluation may take place as an outpatient. Cavernous hemangiomas are venous malformations due to thin-walled, dilated veins that grow with the child, are usually soft with a blue hue, and carry a risk of thrombosis or bleeding. Arteriovenous malformations can be distinguished by their palpable thrill, audible bruit, warmth, and redness. Most importantly, these lesions carry a risk of high-output cardiac failure (12).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of neck mass can be organized according to suspected etiologies (Table 241.5).

TABLE 241.5
Etiologies of Pediatric Neck Masses

Etiology	Typical Presentation
Inflammatory	
Reactive lymphadenopathy (secondary to systemic infection)	Superficial, mobile, tender nodes, fever, other systemic symptoms of illness, i.e., sore throat, vomiting, etc.
Typical causes: EBV, CMV, toxoplasmosis	
Lymphadenitis secondary to local head/neck infection	Erythematous, tender node, fever, may drain
Typical causes: Streptococcal, staphylococcal, mycobacterial, *Bartonella henselae* (catscratch disease), fungal, tularemia	
Sarcoidosis	Firm, enlarged node, +/– fatigue, cough
Sialadenitis	Enlarged, tender gland, parotid often obscures angle of jaw
Retropharyngeal abscess	Neck fullness, torticollis, adenopathy, sore throat, difficulty swallowing/handling secretions
Congenital	
Cystic hygroma (lymphangioma)	Soft swelling, often posterior triangle
Hemangioma	Red or blue soft mass
Thyroglossal duct cyst	Midline, moves with tongue protrusion
Branchial cleft cyst	Most commonly from second arch, mass inferior to mandible and anterior to sternocleidomastoid muscle
Dermoid cyst	Thin walled, may contain fatty or horny masses or hairs
Laryngocele	Generally lateral, compressible neck bulge from anomalous air sac communicating with larynx; can be acquired; cough, hoarseness
Thymic cyst	Generally unilateral and left sided, rare
Neoplasms	
Keloid scars	Hypertrophied tissue overlying area of trauma or surgical site
Benign	
Fibroma, lipoma	Can present in any location, fibromas may be firm/rubbery or soft loose connective tissue, lipomas are comprised of soft, fatty tissues
Thyroid nodule	Generally midline or anterior neck triangle, may or may not have abnormal TFTs
Malignant	Lymphadenopathy, firm, nonmobile, matted, or enlarged >2–3 cm nodes, fevers, weight loss, night sweats, fatigue, bone pain, failure to thrive
Lymphoma	
Leukemia	
Rhabdomyosarcoma	
Neuroblastoma	
Nasopharyngeal squamous cell carcinoma	Respiratory compromise, voice change, epistaxis
Salivary gland tumor	Swelling overlying salivary gland
Thyroid tumor	Anterior neck, +/– abnormal TFTs, weight loss, generalized lymphadenopathy
Metastasis	

ED EVALUATION

Diagnostic evaluation begins with a thorough history and physical examination. The child's overall appearance, the location of the neck mass, the appearance of the pharynx, and the patency of the airway all help guide the clinician's next steps. In most well-appearing children, infectious and inflammatory causes predominate and little further diagnostic testing is required. When reactive lymphadenopathy or lymphadenitis is suspected, a thorough investigation of the head and neck, including the tympanic membranes, pharynx, and skin, should be performed. In patients with fever, tonsillar erythema, and exudate, a rapid streptococcal antigen test may be diagnostic. In young children with suspected infectious mononucleosis (lymphadenopathy, fever, pharyngeal erythema, enlarged spleen), a CBC may reveal atypical lymphocytes, which support the diagnosis. In adolescents, heterophile antibody testing (monospot) can be helpful, but in younger children, EBV-specific serologies must be obtained because heterophile antibodies are often falsely negative in children less than 12 years of age (up to 50% false-negative rate) (13). Erythrocyte sedimentation rate and C-reactive protein measurements can be helpful in tracking infections, but are not necessary in well-appearing children. If there is a draining mass, a Gram stain and culture may guide therapy. Well neonates with a firm mass overlying the lower third of the sternocleidomastoid muscle (with or without torticollis) are likely to have fibromatosis colli, a clinical diagnosis confirmed with ultrasound (US). Treatment is physical therapy.

In the ill-appearing child without airway compromise a complete blood count, blood cultures, CRP, ESR, and x-rays of the neck and chest may help to initially guide diagnosis. Further testing should be based on history (exposures, duration of illness, and review of systems) and physical examination findings. In the ill-appearing child with evidence of airway compromise, x-rays of the neck (AP and lateral soft tissue) and chest can help assess the patency of the airway and lung fields (14). If there is respiratory failure, the airway should be secured by the most experienced operator, with equipment available for an emergent surgical airway (15).

In children with suspected malignancy, a complete and differential blood count is indicated, as well as a screening chest x-ray for the presence of a mediastinal mass. For suspected thyroid masses, thyroid function testing is recommended.

In addition to plain films (particularly the lateral neck film, which can quickly assess for potential airway compromise), US is the initial imaging modality of choice in children (14,16). US is readily available, can be interpreted quickly, does not involve radiation exposure, and is noninvasive. US is particularly useful in children, given their smaller neck size and less prominent subcutaneous fat, allowing for improved sonographic penetration and resolution compared to adults (14). When additional imaging is needed, magnetic resonance imaging and computed tomography (CT) are both useful for defining anatomy. CT is usually readily available, has a short study time that may obviate the need for sedation in younger children, and allows for excellent assessment of bone involvement. However, these benefits must be balanced against the risks of ionizing radiation. MRI is excellent for assessment of soft tissues and carries no radiation risks, but may have limited availability and usually requires sedation.

CRITICAL INTERVENTIONS

- Most well-appearing children with neck masses have lymphadenopathy or lymphadenitis that requires little intervention beyond consideration of antibiotic therapy if a bacterial origin is suspected.
- Antibiotics providing coverage of common head and neck pathogens should be instituted for neck masses that appear infected or for children who appear systemically ill.
- Cultures of neck drainage or blood cultures in systemically ill patients should be obtained prior to antibiotic therapy to tailor the antibiotic choice.
- Incision and drainage of neck masses is not recommended without a definitive diagnosis having been made; this may lead to fistula formation in the case of congenital malformation, or may seed the incision tract in the case of tumor.

- Lymphadenopathy that has persisted beyond several weeks or that is unresponsive to treatment should be considered a potential malignancy or atypical infection, and warrants imaging and consultation.

DISPOSITION

Well-appearing children without airway compromise may be managed as outpatients with appropriate follow-up. Most children with lymphadenitis can be prescribed outpatient antibiotics with primary care follow-up. In the stable child with evidence of a congenital malformation, referral to a pediatric surgeon or otolaryngologist is recommended. Ill-appearing children should be admitted to the hospital with airway support and antibiotics as indicated.

Common Pitfalls

- Failure to recognize impending respiratory failure from airway obstruction due to a neck mass.
- Ordering a CT scan of a neck mass when US or MRI is available and appropriate.
- Incision and drainage of a neck mass in the absence of a definitive diagnosis.
- Failure to recognize possible superinfected congenital malformations.

CHAPTER 242
Limp

Margaret S. Wolff

Limp represents any alteration in gait and is a common reason for presentation to the emergency department (ED) for children (1). The majority of cases are the result of trauma, but a lesion of the central nervous system, spine, peripheral nervous system, intra-abdominal contents, hip, knee, ankle joints, feet, or any of the weight-bearing long bones can lead to an alteration in gait (2,3). This chapter discusses the approach and evaluation of the child with limp in the ED.

CLINICAL PRESENTATION

A detailed history and physical examination are essential in making the correct diagnosis. The caregiver and child should be questioned regarding any temporal relationships, patterns related to physical activity, posture during sleep, and the location of pain. In the nonverbal child, the parents may be able to localize the source of the child's limp. A history of an acute traumatic event, such as a fall, twisting injury, direct blow, or penetration by a foreign body, should be obtained. A history of recent fever, current or recent antibiotic use, antecedent infectious process, or other ill exposures may help to determine an inflammatory or infectious etiology. Historical features which may suggest an etiology of the limp are listed in Table 242.1.

TABLE 242.1
Historical Features of Pediatric Limp

History	Possible Diagnosis
Abdominal pain	Acute surgical abdomen
	Inflammatory bowel disease
	Pelvic inflammatory disease
Back pain	Diskitis
	Pathologic fracture
	Psoas abscess
	Vertebral osteomyelitis
Bleeding disorder	Hemarthrosis
Fever	Infection
	Malignancy
	Rheumatologic disorder
Morning stiffness	Rheumatologic disorder
Pain at night	Malignancy
Preceding sore throat	Acute rheumatic fever
Radicular pain	Nerve involvement
Recent diarrheal illness	Reactive arthritis
Recent intramuscular injection	Inflammation
	Infection
Sickle cell disease	Avascular necrosis of femoral head
Testicular pain	Inguinal hernia
	Testicular torsion
Tick bite or erythema migrans	Lyme disease

In the preschool-aged child, the initial examination can be conducted with the child on a parent's lap. Begin with inspection and evaluate the position of the patient at rest. Examine the skin for evidence of hemorrhagic diathesis, occult trauma, penetrating wounds, rash, or infection. Soft tissue swelling and skin changes may suggest pyoderma, cellulitis, or a deeper plane infection. Evaluate for asymmetry of gluteal, thigh, and popliteal creases. Effusion or distension of the joint capsules of the hip, knee, or ankle may also aid in the diagnosis.

Only after inspection should the physician palpate for localized induration, warmth, or tenderness near the bones, particularly metaphyseal regions of long bones. Assess the degree of restriction of flexion, extension, abduction, and rotation. Palpate the spine in the midline, looking for paraspinal muscle spasm or scoliosis. Examine

the feet thoroughly for embedded foreign bodies. If a thorough musculoskeletal examination has not revealed any abnormalities, perform a thorough neurologic examination including deep tendon reflexes, motor strength, cranial nerve function, and sensory deficits or nuchal rigidity. The patient should also be asked to stand and to attempt to walk.

DIFFERENTIAL DIAGNOSIS

Normal gait requires coordinated action of the entire lower extremity; therefore pain, weakness, or dysfunction at any level can lead to gait disturbances. Traumatic and infectious etiologies account for the majority of patients seen in the ED with limp (Table 242.2). Because of their frequency, overt or occult trauma and infectious diseases should be part of the differential diagnosis for any child with an acute gait disturbance (3).

TABLE 242.2
Causes of Limp in Children

Trauma (most common)
- Contusion
- Fracture
- Sprain
- Overuse injury

Infectious
- Diskitis
- Osteomyelitis
- Pyomyositis
- Septic Arthritis

Postinfectious
- Acute rheumatic fever
- Reactive arthritis

Orthopedic
- Legg–Calvé–Perthes Disease (LCP)
- Slipped capital femoral epiphysis (SCFE)

Intra-abdominal pathology

Neuromuscular disorders

Oncologic conditions

Rheumatologic disorders

Conversion disorders

Traumatic Etiologies

In early childhood, a spiral fracture of the tibia or fibula (toddler's fracture) should be considered the probable diagnosis in an afebrile child less than 5 years old who suddenly refuses to walk or place any weight on a single lower extremity. The absence of direct trauma should not cause the physician to rule out the diagnosis, because these fractures may occur as the result of trivial, indirect injury associated with the child's daily activity (4). Older children may limp from stress fractures of the femoral head, tibial tubercle, and tibial or fibular shaft. They also may limp from avulsion of the ischial apophysis, lesser trochanter, or navicular tuberosity, or from lacerations and compression of cartilage plates, fracture of the epiphyseal ossification centers, shaft fractures, and infractions at various levels of the long-bone metaphyses. These traumatic lesions may present singly or in various combinations and may be acute or more chronic (5). Trauma and repeated stress may be important

factors in the genesis of slipped capital femoral epiphysis, transient synovitis, and Legg–Calvé–Perthes disease, three of the most common hip afflictions associated with antalgic gait (6).

Nontraumatic Etiologies

An early presumptive diagnosis for the cause of gait disturbance must be established for a few conditions (Table 242.3). Failing to consider these conditions at the initial encounter may lead to deformity, functional disability, or ultimate patient demise (7). Serious infectious diseases predominate among the nontraumatic conditions that can cause altered gait with serious late complications if not detected early (8). A history of fever should heighten concern for a focal cellulitis of the lower extremity, unifocal septic arthritis of a weight-bearing joint, and osteomyelitis of the femoral or tibial metaphyses (8).

TABLE 242.3
Disease States Associated with Limp that Require Prompt Recognition

Osteomyelitis
Long bone, spine, pelvis
Pyarthrosis
Hip, knee, ankle
Sacroiliac infection
Psoas abscess
Deep-plane infection
Epidural abscess
Intramedullary abscess of the spinal cord
Slipped capital femoral epiphysis
Cord tumor
Guillain–Barré syndrome
Tick paralysis
Meningitis
Encephalitis
Cerebral abscess
Appendicitis

Modified and reproduced with permission from Singer J. Evaluation of acute and insidious gait disturbance in children less than 5 years of age. In: Barness LA, et al., eds. *Advances in Pediatrics*. Vol. 26. Chicago, IL: Year Book; 1979:210.

Pain associated with osteomyelitis of the long bones is primarily located at the affected metaphysis. Direct pressure at the affected metaphysis produces extreme discomfort. Swelling is limited to the immediate metaphyseal area initially, but it can spread rapidly to involve an entire extremity or adjacent periarticular tissue. Joints adjacent to the infected metaphysis may have some limitation of motion caused by voluntary guarding or sympathetic effusion. Neck pain, back pain, and refusal to walk may signal the presence of osteomyelitis of the spine. Fever associated with back, buttock, or hip pain with gait disturbance may be the initial expression of osteomyelitis of the pelvis (9). Children are prone to nontraumatic osteomyelitis, so the diagnosis should receive consideration.

Patients with pyogenic arthritis are usually readily diagnosed because of the protective posturing imposed by joint capsule distention. When there is hip involvement, children assume a characteristic position of comfort (Fig. 242.1). If the knee or ankle is involved, it is erythematous, warm, swollen, and painful to palpate, with limited range of motion. Minimal active motion, extreme

muscle spasm, and pain with passive movement are distinguishing features of pyarthrosis in weight-bearing regions. Rarely, children with pyogenic arthritis can present with more subtle symptoms mimicking transient synovitis (10,11).

FIGURE 242.1 Child with septic hip. He is holding his left lower extremity flexed and externally rotated at the hip, as is characteristic with bacterial infection of the joint. (From Fleisher GR, Ludwig W, Baskin MN. Atlas of Pediatric Emergency Medicine. Philadelphia, PA: Lippincott Williams & Wilkins; 2004).

Children with transient synovitis have a unilateral inflammatory reaction in the hip. These patients usually present with either acute or progressive discomfort in the hip, anteromedial thigh, or ipsilateral knee that eventually leads to an antalgic gait. There may be antecedent minor trauma, recent upper respiratory tract

symptoms, or low-grade fever. A fever of ≤38.5°C should raise the suspicion of septic arthritis. Clinically, this condition may be indistinguishable from Legg–Calvé–Perthes disease. In both cases, children do not appear systemically ill. They choose a position with the thigh flexed, abducted, and externally rotated. They guard the hip during examination and have pain with internal rotation of the hip and, to a lesser extent, with hip extension (6). The peak incidence of Legg–Calvé–Perthes disease is between 5 and 7 years of age (12).

Hip, groin, abdomen, lower back, buttock, or upper thigh pain associated with fever and limping may occur with a psoas abscess. Like patients with septic arthritis of the hip, those with psoas abscess may assume the position of hip flexion, abduction, and external rotation. Rotation of the fully flexed hip is typically pain free. Several findings may differentiate psoas abscess from septic arthritis or osteomyelitis: the presence of abdominal guarding with tenderness in lower quadrants or a palpable mass in the iliac fossa or pelvic floor detectable by rectal examination. Patients also may have bulging of the flank with or without cutaneous edema, scoliosis, immobility of the spine with spasm of the paravertebral muscles, or decreased excursions of the diaphragm (13).

Deep-plane infection refers to suppuration that extends to the depth of fascia or muscle. In necrotizing fasciitis, fat and fascia are destroyed. Muscle is typically uninvolved, and skin, on occasion, may be spared (14). In bacterial myositis, the striated muscle is involved, and there may be localized abscess formation within the muscle (pyomyositis). Clinical features of fasciitis and myositis overlap. Neither disease is common in immunologically intact children. Predisposing conditions include diabetes mellitus, chronic cardiac or pulmonary disease, collagen vascular disease, varicella complicated by pyoderma, and antecedent blunt trauma. Symptoms are often insidious, starting with poorly localized extremity pain that impairs gait. Fever may be absent or only of low grade. Pain out of proportion to the degree of physical findings may be the only clue to the correct diagnosis at the initial encounter (14). Rapidly developing skin changes suggest the diagnosis. These changes

include a localized soft tissue swelling, erythema, and either darker discoloration of the skin (pyomyositis) or bullae formation, and spontaneous sloughing (necrotizing fasciitis). If misdiagnosed at the time of initial presentation, children may return in extremis within 24 to 48 hours in septic shock (14).

In cases of acute or chronic slipped capital femoral epiphysis, deep groin pain and hip, distal medial thigh, or knee pain may be of sudden onset or progressive over weeks. Classically, pain is vague, dull at rest, and exacerbated by ambulation. Children seek comfort by externally rotating the leg when walking. They limp, is often accompanied by a truncal shift with ambulation to accommodate hip abductor weakness. Examination demonstrates a partially flexed, irritable hip maintained in external rotation. Maximal hip flexion is restricted, and complete internal rotation is not possible. Delay in recognition of an acute slip may result in further displacement or may increase the risk for avascular necrosis.

Pathology outside the musculoskeletal system may also present as limp. Patients with uncomplicated appendicitis, or a perforated or abscessed appendix may present with a slow cautious, gait accompanied by flexion of the trunk (15). Hip pain and limp may be the presenting complaints with epidural abscess, but most patients in this instance seek medical attention because of unremitting back pain. At the onset, most patients exhibit fever, headache, malaise, and aching midline back pain. Patients may have tenderness on palpation of the spinous processes at the level of their back pain. Overt cord involvement may be heralded by weakness of voluntary muscles and bowel and bladder sphincters or by sensory abnormalities, most often characterized as ascending anesthesia (16). Limp may be the initial presentation of systemic illness such as acute lymphoblastic leukemia or lymphoma (17). Systemic symptoms such as fever, weight loss, and night time pain may suggest these diagnoses.

ED EVALUATION

ED evaluation should be guided by history and physical examination (Fig. 242.2). When there is a history of trauma or the area of pain

has been localized, radiographs limited to the area of interest have proven diagnostic efficacy. Plain radiographs are specific for fractures, destructive lesions, and avascular necrosis (18–21). Radiographs are often insensitive and unreliable, especially in the early course of patients with toddler's (tibial) fractures, septic hip, osteomyelitis of the long bone or pelvis, sacroiliac joint infection, and intervertebral disk infection.

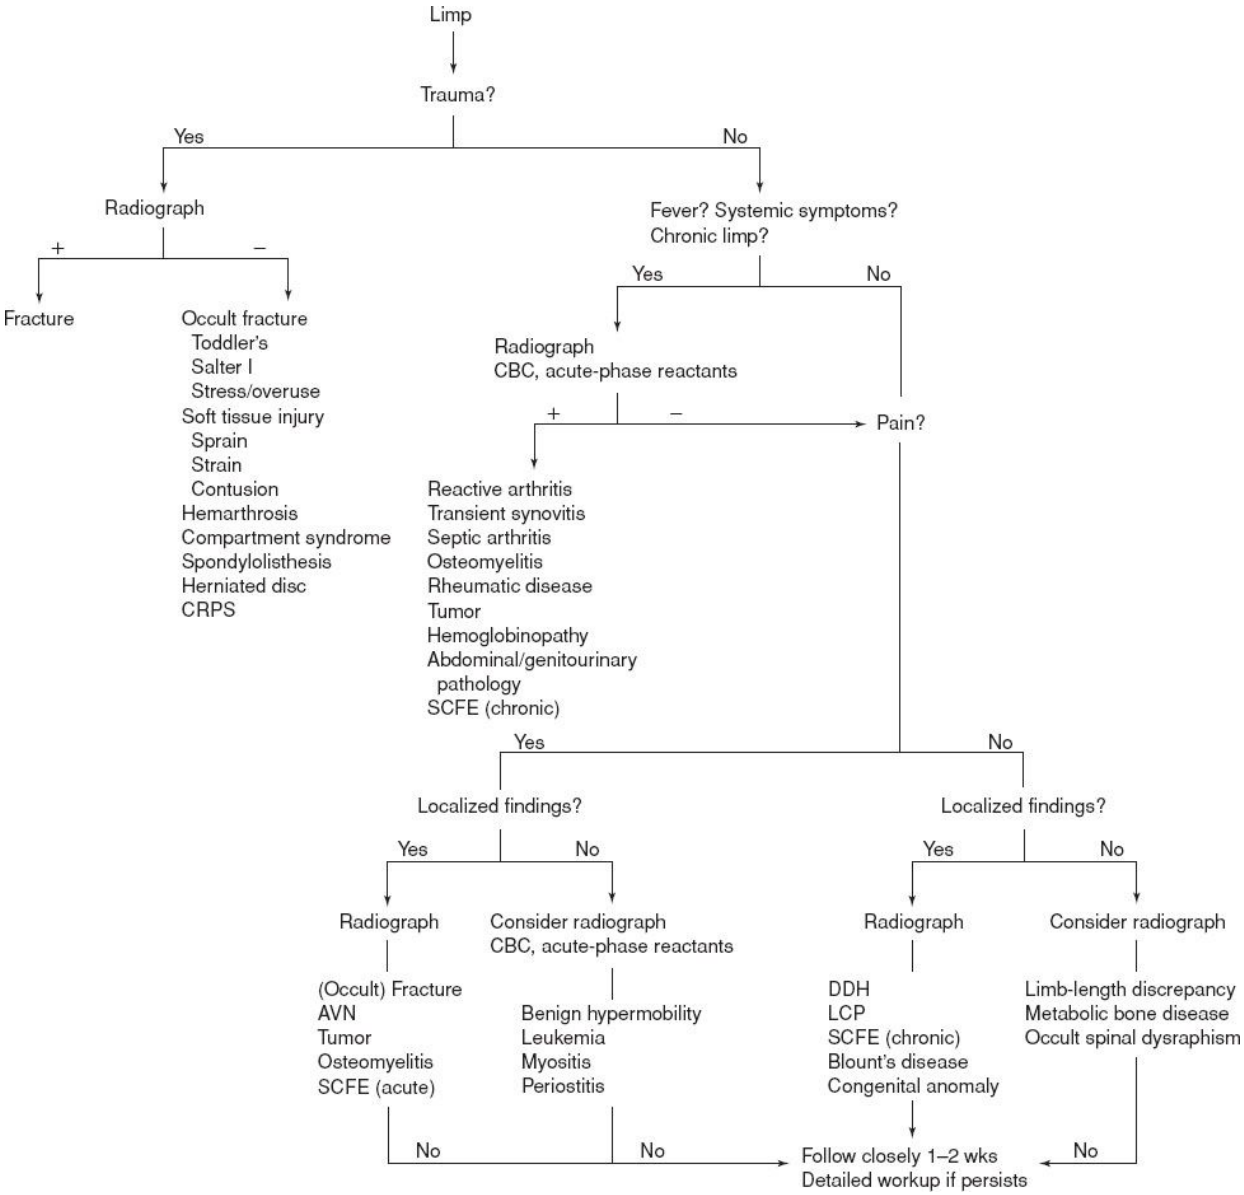

FIGURE 242.2 Algorithmic approach to the child with a limp. CRPS, complex regional pain syndrome; CBC, complete blood count; SCFE, slipped capital femoral epiphysis; AVN, avascular necrosis; DDH,

developmental dysplasia of the hip; LCP, Legg–Calvé–Perthes disease. (From Gary RF, Stephen L, Fred MH, et al. *Textbook of Pediatric Emergency Medicine.* 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2005.)

Patients with fever or systemic symptoms require a more extensive evaluation. Laboratory evaluation should include a complete blood, erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), and blood culture (if febrile). A CRP level >2 mg/dL is consistent with a septic joint or osteomyelitis when the clinical picture is suggestive (11,22–24). It is important to note that fever, leukocytosis, and elevated acute phase reactants may not uniformly accompany infectious diseases associated with gait disturbance (11).

In patients with fever or other systemic symptoms, further imaging is indicated if initial radiographs are negative and the suspicion is high for bacterial infection of the bone, joint, or soft tissue (24). Patients with hip irritability should undergo ultrasonography to assess for presence of an intra-articular effusion (25). Magnetic resonance imaging (MRI) is superior to both plain films and CT scans for soft tissue detail. MRI may be the most sensitive means of establishing an early diagnosis of Legg–Calvé–Perthes disease, differentiating bone infarction from osteomyelitis in the sickle cell patient and benign from malignant bone tumors. MRI may be useful in certain anatomic regions that are difficult to evaluate with plain films (e.g., region of the sacroiliac joint, vertebral bodies, and intervertebral disks) (18).

KEY TESTING

- Plain radiographs of affected extremities
- Blood cultures if febrile
- CBC
- ESR
- CRP
- Ultrasound of hips if indicated
- CT MRI for equivocal cases

ED MANAGEMENT

Rarely, a patient with limp, pseudoparalysis, or paresis requires establishment of an airway or ventilatory support or hemodynamic instability. If present, initiate prompt resuscitation prior to proceeding with evaluation of limp. Neurologic deficits may be rapidly progressive in a few conditions associated with gait disturbance. Continuous monitoring of neurologic status is warranted for patients suspected of having Guillain–Barré syndrome, poliomyelitis, acute transverse myelitis, tick paralysis, brain abscess, meningitis, or cerebral vascular accident.

For all patients with limp, ensure that any associated pain is well controlled. Additional management will vary depending on the history, physical and evaluation. Patients with traumatic injuries may require splinting, reduction of fractures, or operative repair, and consultation with orthopedics can be beneficial. Patients with fever should receive antibiotics if a source is located or if the patient is hemodynamically unstable. Septic joints require urgent arthrocentesis and consultation with orthopedics. Patients with suspected osteomyelitis or deep soft tissue infections not identified in the ED require admission for further evaluation such as MRI. In patients with presumed transient synovitis, a dose of ibuprofen can markedly improve symptoms and aid in diagnosis.

CRITICAL INTERVENTIONS

- Obtain plain radiographs in children with traumatic limp.
- Perform a thorough physical examination, including neurologic examination, in patients with nontraumatic limp.
- Order CBC, acute phase reactants, and blood culture for children with fever and limp.
- Patients with hip irritability and fever require prompt ultrasonography, and arthrocentesis if hip effusion present.

DISPOSITION

Admission is warranted for children with gait disturbance in certain circumstances. All patients who appear to have a serious bacterial

infection require admission. Admission is warranted for all patients with neurologic abnormalities, such as altered consciousness, cranial nerve involvement, subjective or objective sensory disturbance, ataxia, alteration of sphincter tone, urinary retention, altered deep tendon reflexes, or loss of voluntary movement. Admit patients with gait disturbance who may have injuries due to nonaccidental trauma in consultation with child protective services.

Common Pitfalls

- Think of trauma when there is an abrupt onset of gait disturbance without prodromal events in a previously healthy child.
- De-emphasize the history of trauma, even if witnessed, when fever or systemic symptoms are present; this scenario suggests serious bacterial infection.
- Fever, leukocytosis, and acute phase reactants may not uniformly accompany infectious diseases associated with gait disturbance.

CHAPTER 243 Hematuria and Dysuria

Tiffani J. Johnson and Rhett Lieberman

HEMATURIA

Hematuria is the presence of blood in the urine, which can be gross (visible to the naked eye) or microscopic. Microscopic hematuria is defined as the presence of 3 to 5 RBCs/HPF on at least two of three examinations over a 2- to 3-week period, and is a common finding in the pediatric population, with a prevalence of 0.5% to 2%, although less common than in adults, where the prevalence is up to 21%. Gross hematuria presents as a discoloration of the urine that is either red/pink or cola or tea colored. It is important to note that a small amount of blood (1 mL in 1,000 mL of urine) can cause discoloration of the urine (1). Gross hematuria is noted in about 0.1% of children, as compared to 2.5% in adults (2). Distinguishing emergent reasons for evaluation in the pediatric patient is essential for the emergency practitioner.

CLINICAL PRESENTATION

Microscopic hematuria is often an incidental finding in children during evaluation for genitourinary (GU) symptoms. The primary tool for screening is a urine dipstick; a result of blood 1+ and greater is considered positive. The dipsticks used for detection of blood in the urine are very sensitive in detecting red blood cells (RBCs) and minute amounts of free hemoglobin and myoglobin. Dipstick screens should be confirmed with microscopic examination of the urine to exclude false-positive and false-negative results.

DIFFERENTIAL DIAGNOSIS

The causes of hematuria are numerous, and in the pediatric population are more often medical than surgical in nature (3). In developing a differential diagnosis, in addition to classifying hematuria as gross or microscopic, clinicians must be able to differentiate the origin of the hematuria. In children gross hematuria is often glomerular in origin. Glomerular bleeding tends to be associated with cola- or tea-colored urine (30% of patients), whereas bleeding from the lower tract and bladder presents with red- or pink-colored urine. Furthermore, with glomerular hematuria there are often findings of proteinuria, red cell casts, and red cell dysmorphology, coupled with systemic findings such as hypertension and edema (1,4). The passage of blood clots usually points to the bladder or urethra as the source of bleeding (3,5).

Acute glomerulonephritis (AGN) results from immunologic effects on the glomerular tissue and is divided into three broad categories: postinfectious, due to intrinsic renal disease, and due to systemic disease (Table 243.1). Postinfectious acute glomerulonephritis (PIAGN) is a common cause of pediatric glomerulonephritis and the most common cause of glomerular gross hematuria in the pediatric patient. It has a peak incidence between the ages of 2 and 6 years and frequently follows streptococcal infections of the skin or pharyngitis with certain nephrogenic strains of group A β-*hemolytic streptococci.* Characteristically, there is a latent period between the streptococcal infection and the onset of nephritis, which can be 8 to 14 days for pharyngitis and 14 to 21 days for skin infections (4,6).

TABLE 243.1
Causes of Glomerulonephritis

Postinfectious	Renal	Systemic
Bacteria: Streptococcus (PSAGN), Staphylococcus, mycobacteria, Salmonella	Membranoproliferative glomerulonephritis	Wegener granulomatosis
Viral: CMV, Coxsackie, EBV, hepatitis, rubella, mumps	IgA nephropathy (Berger disease)	Hypersensitivity vasculitis
Fungal: Coccidioides immitis	Idiopathic rapidly progressive glomerulonephritis	Cryoglobulinemia
Parasite: Plasmodium spp, Schistosoma mansoni, Toxoplasma gondii, filariasis, trichinosis, trypanosomes		Systemic lupus erythematosus Polyarteritis nodosa Henoch–Schönlein purpura Goodpasture syndrome

PSAGN, Post-streptococcal acute glomerulonephritis; CMV, cytomegalovirus; EBV, Epstein–Barr virus.

Urinary tract infection (UTI) represents the most common cause of gross hematuria and is often associated with dysuria, frequency, or abdominal pain (7). A history of recent trauma, including catheterization, masturbation, urethral foreign bodies, or recent strenuous exercise (running, bicycle riding) can explain transient hematuria (8). Any past history of renal colic or a family history of nephrolithiasis or hypercalciuria should be elicited. Specific pulmonary symptoms, such as hemoptysis (Goodpasture syndrome), or the triad of sinusitis, AGN, and pulmonary infiltrates (Wegener granulomatosis) may provide important clues to a diagnosis.

Pseudohematuria is caused by substances other than blood that discolor the urine (Table 243.2). This may include oxidizing contaminants, such as bacterial peroxidases from a UTI, or a delay in reading the dipstick. Newborns often present with the parents' concern for a red or pink discoloration in the front of the diaper, often referred to as "brickdust urine," which is caused by urate crystals deposited in the diaper. Certain foods (e.g., beets, blackberries, rhubarb), and medications (e.g., rifampin, cefdinir) can also cause urine discoloration that is mistaken for hematuria (4,7). A positive dipstick reaction in the absence of RBCs on microscopy can be caused by myoglobinuria (rhabdomyolysis) or hemoglobinuria (seen in conditions causing hemolysis). In the menstruating girl, vaginal bleeding can be confused with urinary

blood. A catheterized urine specimen may be necessary to determine the source of the bleeding. It should also be noted that a false-negative dipstick reading can occur when the urine has a high specific gravity or contains large amounts of reducing substances, such as ascorbic acid.

TABLE 243.2
Cause of Pseudohematuria

Myoglobinuria (seen in rhabdomyolysis)
Hemoglobinuria (seen in conditions causing hemolysis)
Oxidizing contaminants (e.g., bacterial peroxidase from UTI)
Delay in reading dipstick
Foods (e.g., beets, blackberries, rhubarb)
Medications (e.g., rifampin, cefdinir)
Brickdust urine (caused by urate crystals in the diaper)
Vaginal bleeding

The differential diagnosis for childhood hematuria is listed in Table 243.3, and can be remembered by using the alphabetic sequence A through I (9).

TABLE 243.3
Differential Diagnosis for Childhood Hematuria

Anatomy/vascular (renal cysts, arteriovenous malformations, obstruction with hydronephrosis)
Boulders (renal stones, hypercalciuria and hyperuricosuria)
Cancer (Wilms tumor or adenocarcinoma and infiltration of the kidney by leukemia or solid tumors)
Drugs/Dehydration (over-the-counter or illicit drugs, methicillin, cyclophosphamide, anticoagulants)
Exercise-induced hematuria
Foreign body, familial (Alport) or factitious
Glomerulonephritis (GN):
Primary GN: poststreptococcal, IgA nephropathy (Berger Disease), membranoproliferative
Secondary GN: Henoch–Schönlein Purpura, hemolytic–uremic syndrome, systemic lupus erythematosus
Hematology (hemoglobinopathy, coagulopathy)
Infectious (cystitis caused by adenovirus, tuberculosis, schistosomiasis in patients with recent travel to the Middle East or Africa)

ED EVALUATION

The diagnostic approach to the pediatric patient with hematuria should incorporate specific elements of both the past and family history. The workup differs from that in adults since renal and urologic malignancies are far less common (10,11). The history should identify antibiotics use, chemotherapy, radiation for malignancies, exposure to tuberculosis, or the use of over-the-counter medications, some of which can cause interstitial nephritis. Rash or arthritis can be found in systemic vasculitides such as systemic lupus erythematosus (SLE) or Henoch–Schönlein purpura (HSP). Umbilical catheterization in the neonatal period, often in premature infants, can cause renal vein or artery thrombosis, which may result in hematuria (12). Inquiry into family history can uncover other potential etiologies. For example, a family history of hearing deficits and renal failure may suggest Alport syndrome. Other diseases that have a familial association include SLE, sickle cell anemia, hemophilia, IgA nephropathy, and other coagulation factor deficiencies.

The physical examination is often nonspecific, but several elements deserve attention and are useful in diagnosis and management. An elevated blood pressure should alert the physician to the possibility of a more severe underlying condition, such as aortic interruption or intrinsic renal disease. The child's height and weight should be plotted and past values should be carefully reviewed to detect failure to thrive associated with long-standing acidosis or chronic renal insufficiency. Evaluation for periorbital and genital edema is important.

Pulmonary findings on auscultation, in addition to exercise intolerance or dyspnea, may provide clues to fluid overload. Costovertebral angle tenderness may indicate a UTI. Recent trauma maybe suggest by findings of flank bruising and pain. Examination of the abdomen for masses is critical for the identification of renal and urologic malignancies (Wilms tumor being the most common in pediatrics), polycystic kidneys, or hydronephrosis (11). The examination of the skin and joints may provide evidence of arthralgias and pallor or rashes, which may be significant in diseases such as hemoglobinopathies, leukemia, HSP (petechial or

purpuric lesions on the lower extremities), or SLE (malar rash) (7). The genital examination should be included to identify abuse or trauma, discharge, or meatal stenosis, all of which can cause hematuria.

The child with a history of flank, back, or abdominal trauma and gross hematuria should undergo renal imaging to identify renal injury. Ultrasound is useful for detecting free fluid in the abdomen in the case of trauma, but computed tomography (CT) provides more specific information for diagnosing and grading renal injuries. Gross hematuria is not the only presentation for significant high-grade renal injuries. In fact, significant injuries may present with microscopic hematuria or an entirely normal urinalysis. Therefore, the decision to pursue imaging for renal injuries should not be based on urinalysis alone, but on a combination of clinical status, physical examination findings, and mechanism of injury (13). A high index of suspicion must be maintained for lesions of the urinary tract in patients with gross hematuria after minimal-force blunt abdominal trauma. Some authors recommend a CT scan of the abdomen and pelvis for patients with 50 or more RBCs on urinalysis, hypotension at the time of emergency department (ED) presentation, or a serious mechanism of injury such as high-speed motor vehicle accident deceleration injuries (5). If blood is noted at the urethral meatus, a retrograde urethrogram must be done prior to catheterization to verify urethral integrity.

Dysuria and urinary frequency, or the presence of systemic signs (fever, vomiting, and abdominal pain), should suggest the possibility of a UTI, including pyelonephritis, and a screening urinalysis and urine culture must be sent. The child with gross hematuria and severe episodic flank or abdominal pain should be evaluated for urolithiasis. The literature on using radiography to diagnose urolithiasis in pediatrics describes varying sensitivities and predictive values for different radiologic modalities. Plain radiography is insufficient to detect stones and ultrasound can detect intrarenal stones, especially those more than 5 mm in diameter (14). Noncontrast CT is the gold standard, but concerns about the long-term effects of radiation exposure have led many

clinicians to reserve CT for patients with persistent or refractory symptoms, or a nondiagnostic US. Urologic consultation is appropriate if a stone is detected. Since a metabolic abnormality can be identified in 40% to 50% of cases of urolithiasis in children, a basic metabolic panel and urine calcium determination are an appropriate part of the initial workup (15,16).

Gross hematuria combined with the presence of proteinuria suggests glomerulonephritis. Proteinuria should not exceed 2+ if the only source of protein is from the blood. Postinfectious glomerulonephritis is the most common cause of acute nephritis in the pediatric population. Pertinent laboratory evaluation includes a complete blood count (hemolytic–uremic syndrome), and culture from the throat and skin should be sent in an effort to isolate a nephrogenic strain of streptococcus, although these cultures are usually negative at the time of diagnosis. Elevated anti-streptolysin O (ASO) titers suggest recent infection (2 to 6 weeks); however, the ASO titer may not rise after streptococcal pyoderma. Anti-DNase B can be elevated for up to 6 months after infection, and is the best single test to detect recent streptococcal infection. The complement C3 level is low in acute poststreptococcal glomerulonephritis, membranoproliferative glomerulonephritis, and SLE, but returns to normal in 6 to 8 weeks (4,6). Further immunologic workup, including antinuclear antibody tests, may be helpful if a diagnosis of underlying systemic disease is being entertained (7).

Less common causes of gross hematuria include hypercalciuria, nephrocalcinosis, sickle cell trait, and glomerular basement membrane defects. Diagnosis begins with a urine Cr/Ca ratio or a 24-hour urinary calcium excretion, serum creatinine, and renal sonography. Consultation with a pediatric nephrologist is recommended if the underlying etiology in unclear on the initial evaluation.

KEY TESTING

- Urinalysis with verification of hematuria by microscopic evaluation

- For potential renal trauma: CT or ultrasonography, CT is preferred for more accurate grading of injury
- For nephrolithiasis: ultrasonography or CT, metabolic panel, and serum calcium
- For glomerulonephritis: skin culture, throat culture, ASO titre, anti-DNase B and C3 complement levels; CBC for possible HUS

ED MANAGEMENT

Management of hematuria depends on the specific etiology involved. Pain management must be addressed in the uncomfortable child. Ketorolac and morphine are the mainstays of analgesia for renal colic. Medical expulsive therapy with agents such as tamsulosin has not been well studied in the pediatric population (17). Asymptomatic hematuria does not require acute ED management, with the exception of UTI, in which appropriate antibiotic therapy is needed (see Chapter 288).

In PSAGN, no specific therapy has been found to influence healing of the glomerular lesions, and much of the treatment is supportive. Antibiotics do not alter the ultimate course of the initial streptococcal disease (with the exception of prevention of rheumatic fever) but may decrease the spread of nephrogenic strains of streptococcus in patients with positive cultures. Thus, penicillin should be administered to the nonallergic patient. For the child with acute renal failure, hypertension, or hyperkalemia, appropriate treatment should be initiated promptly, in consultation with a nephrologist (18).

Up to 85% of patients with postinfectious glomerulonephritis have edema and hypertension, in addition to hematuria, and up to 10% to 30% may have hypertensive encephalopathy presenting with headache, nausea, vomiting, seizures, or transient cortical blindness (6). For hypertensive emergencies in children with PSAGN, therapy should be gradual and controlled. Drugs such as diazoxide, hydralazine, labetalol, loop diuretics, and calcium channel blockers are increasingly chosen because of their quick onset of action. However, decreasing blood pressure by more than 20% to 25% can

cause decreased cerebral perfusion and has the potential to cause stroke. In patients with glomerulonephritis that is nonstreptococcal, corticosteroids or cytotoxic agents may be prescribed in consultation with a nephrologist.

Less common causes of hematuria in children include coagulation abnormalities and some anatomic or vascular problems (7). These, and other conditions requiring advanced workup (Table 243.4), should be referred to a pediatric nephrologist or urologist.

TABLE 243.4
Evaluation of the Child with Hematuria

Initial Evaluation of child with hematuria
History/family history
Physical examination
Urinalysis with microscopy, protein measurement
Red blood cell morphology
Urine culture
Calcium–creatinine ratio
Sickle cell screen, if applicable
Complete blood count, creatinine, and blood urea nitrogen levels
Renal ultrasound
Advanced evaluation of child with hematuria
Urine of first-degree relatives
Complement level (membranoproliferative, SLE, postinfectious glomerulonephritis)
Anti-streptolysin O and anti-DNAse B (Acute poststreptococcal glomerulonephritis)
Antinuclear antibody (SLE)
Audiogram (Alport syndrome)
Antiglomerular basement membrane antibodies
Antineutrophil cytoplasmic antibodies (Active crescentic glomerulonephritis)
Tuberculosis testing
Renal biopsy

SLE, systemic lupus erythematosus.

CRITICAL INTERVENTIONS

- The decision to order renal imaging after blunt trauma should be based on clinical status, history, and mechanism of injury and not on the urinalysis alone.
- Acute management of pediatric hypertensive emergencies should be gentle and controlled, often in consultation with a pediatric

nephrologist.

DISPOSITION

Referral to a pediatric nephrologist should occur for children with gross hematuria, coexisting significant proteinuria, hypertension, abnormal kidney function tests, persistent hypocomplementemia, findings suggestive of a systemic disease, or a family history of glomerulonephritis, nerve deafness, chronic renal failure, end-stage renal disease, or familial hematuria. If parental anxiety is high, referral to a pediatric nephrologist may help alleviate fears and serve as additional reassurance to the family that dangerous and treatable conditions have been ruled out by the emergency physician. Parents are often concerned that their child is losing large amounts of blood due to the color of the urine, and they should be reassured and reminded that as little as 1 mL of blood in 1,000 mL of urine can make the urine red (3,7,19).

Patients with newly diagnosed renal disease should be admitted with pediatric nephrologist consultation, given the possible complications, including hypertension, hyperkalemia, and acute renal failure.

It is important to remember the most common causes of microscopic hematuria without casts or proteinuria are benign and do not require immediate treatment. The overall prognosis for these children is very good. A poor prognosis is, however, associated with proteinuria at presentation, persistent hematuria, and hypertension.

Common Pitfalls

- Failure to perform a urine dipstick followed by formal urinalysis to confirm the presence of blood in the patient with “red urine” can lead to unnecessary further laboratory testing.
- Failure to obtain relevant information such as a history of recent pharyngitis, trauma, or renal stones
- Failure to detect proteinuria, hypertension, or subtle signs of fluid overload

- Failure to recognize that the presence of polymorphonuclear leukocytes and renal epithelial cells may be the only abnormalities in early AGN
- Failure to include AGN in the differential diagnosis of hematuria, particularly when there are other signs such as edema
- Failure to send a urine culture when there are signs and symptoms of UTI

DYSURIA

Many GU conditions can present with dysuria, the most common being UTI, sexually transmitted infection (STI), and vaginitis. Rarely, dysuria may be a presenting complaint associated with systemic disease.

CLINICAL PRESENTATION

Dysuria is defined as pain with urination and may be the chief complaint of a verbal child ($\geq$2 years), or the perceived complaint reported by the parent of a preverbal child who cries with urination or diaper changes. The clinical presentation of dysuria varies depending on the underlying cause.

DIFFERENTIAL DIAGNOSIS

Table 243.5 outlines common causes of dysuria.

TABLE 243.5
Causes of Pediatric Dysuria

- Disorders of the Genitourinary Tract
  - Urinary Tract Infections: pyelonephritis, cystitis (bacterial and viral)
  - Sexually Transmitted Infections: Neisseria gonorrhea, Chlamydia spp, herpes simplex virus, syphilis
  - Vulvovaginitis: bacterial (Candida, Trichomonas, Gardnerella), atopic or chemical irritant (bubble bath, detergent, fabric softener)
  - Trauma: masturbation, sexual activity, minor injury
  - Foreign body
- Systemic Causes
  - Stevens–Johnson Syndrome
  - Behçet disease
  - Reactive arthritis
- Rare Causes
  - Urinary stones
  - Idiopathic hypercalciuria/hyperuricosuria
  - Dysfunctional voiding
  - Urethral stricture

UTI is defined as infection of the bladder (cystitis), kidney (pyelonephritis), or both. UTIs account for 5% to 14% of pediatric ED visits in the United States (20). The clinical presentation varies depending on the age of the child. Preverbal children are more likely to present with fever and nonspecific symptoms such as vomiting or fussiness, while older children are more likely to present with specific urinary symptoms such as dysuria, frequency, urgency, and suprapubic abdominal pain. Findings most useful for identification of a UTI include history of a previous UTI, fever, suprapubic tenderness, and lack of circumcision in males. In verbal children, abdominal pain, back pain, dysuria, frequency, and new-onset incontinence may be findings associated with UTI (21). Pyelonephritis is typically associated with a fever $\geq$38.5°C, while children with cystitis are less likely to have fever.

STIs are a common cause of dysuria; the reported ED prevalence of STIs in symptomatic adolescent patients has been as high as 26% (22). *Neisseria gonorrhoeae* and *Chlamydia trachomatis* are the most common causes in adolescents while *Trichomonas vaginalis* occurs less commonly. Urethritis is a localized inflammation of the urethra, usually caused by infection. When left untreated, up to 40% of STIs will lead to more serious conditions including pelvic inflammatory disease (PID), chronic pelvic pain, and even infertility (22). In

addition to urethritis and PID, ulcerative STIs, such as herpes or syphilis, may present with dysuria.

Vulvovaginitis presents with vaginal discharge and vulvar irritation, typically with redness, burning, itching, and soreness. Dysuria is usually due to the pruritus and excoriation. Recurrent vulvovaginitis can also be bacterial, and occurs most commonly in prepubertal girls aged 2 to 7 years, due to low estrogen levels (23). Infections from *Candida, Trichomonas,* and *Gardnerella* are uncommon in prepubertal girls. Young girls can have vulvar irritation without virginal discharge, usually due to atopic or irritant dermatitis. Common local irritants include fragranced soaps, bubble bath, laundry detergents, and fabric softeners. Physical examination is often unremarkable, or may reveal mild genital erythema without discharge. In some cases, excoriations caused by vulvar irritation may lead to labial adhesions as the skin heals.

Pruritus due to pinworm infection may also be reported as dysuria. Symptoms tend to be worse at night, when worms emerge from the anus and lay eggs around the anus and vaginal area. Nausea, vomiting, and abdominal pain may develop if there is a large worm burden.

Additional causes of dysuria in the pediatric population worthy of consideration based on the history and physical examination include minor trauma from self-exploratory behavior, masturbation, or sexually activity. A foreign body may cause pain or pruritus that may be reported or misinterpreted as dysuria. Examples include retained toilet paper from poor hygiene, or small objects, such as a bead or toy, in a younger child. Rarer causes include urinary stones, idiopathic hypercalciuria or hyperuricosuria, dysfunctional voiding, and urethral structure.

Systemic conditions as a cause of dysuria are uncommon, but may be potentially serious. The mucocutaneous lesions of Stevens–Johnson syndrome can involve the genitalia. Reactive arthritis presents with arthritis, conjunctivitis, and urethritis, and occurs more commonly in sexually active males. Behçet disease is a multisystem vasculitis that can present with oral and genital ulcers,

as well as ocular, joint, gastrointestinal, skin, and neurologic involvement.

ED EVALUATION

The history is critical in guiding the approach to a child with dysuria. Important points to note include associated GU symptoms such as hematuria, frequency, urgency, hesitancy, incontinence, burning with urination, or vaginal or penile discharge. Systemic symptoms, including the duration and height of fever, joint pain, ocular complaints, or rash, are important to identify. Vomiting, abdominal pain, suprapubic pain, and back pain should also be noted. All adolescents should have a sexual history obtained with the parents outside the room. However, the sexual history may be unreliable in this population, so history alone should not guide management decisions. A previous history of UTI and STI should also be documented. The physician should inquire about any exposures to chemical irritants that may cause dysuria (e.g., perfumes, soaps, bubble bath, laundry detergents, or fabric softeners).

In younger children, consider beginning with auscultation of the heart and lungs before beginning any potentially uncomfortable portions of the examination. Care should be taken to note any oral lesions, which can be seen with systemic illness such as Stevens–Johnson syndrome or Behçet disease. Examine the abdomen for tenderness over the suprapubic region and right, and left lower quadrants, which may suggest cystitis. Tenderness on palpation at the costovertebral angle suggests pyelonephritis. The skin should be examined for rashes.

A GU and perianal examination should be performed to evaluate for discharge, lesions, vesicles, ulcerations, gross anatomical abnormalities (e.g., labial adhesions), or the presence of a foreign body. In males, the scrotum should be examined for swelling, redness, or tenderness to palpation. If the patient is uncircumcised, the foreskin should be examined for signs of inflammation. The female GU examination should be performed in the frog-leg position

on the examination table, or in a less cooperative child, on the parent's lap. The child should lie on her back, bend the knees, place the feet together, and open the legs like a frog with the lateral aspect of knees touching the examination table if possible. Inspection should be performed using labial traction by gently grasping the labia majora and pulling laterally and downward to improve visualization. If better visualization of the vaginal vault is needed, consider the knee-chest position by having the child lie on her face and chest with the buttocks in the air and with the knees bent and 6 to 12 in apart. The underwear should also be inspected for signs of discharge.

In addition to the external GU examination, a bimanual examination should be performed in all sexually active adolescent females to assess for cervical motion tenderness or uterine or adnexal tenderness. In the setting of advanced diagnostic testing for STIs, invasive speculum examinations are not always routinely indicated for dysuria. The speculum examination should be performed in adolescent females with accompanying vaginal bleeding, suspected foreign body, pregnancy, or persistent symptomatic vaginal discharge.

The physician must be able to interpret the results of the urinalysis, initiate antibiotic treatment when appropriate, and ensure follow-up of urine culture results. The need for further diagnostic studies should be guided by the history and physical examination, coupled with the physician's index of suspicion for other entities.

UTI is diagnosed based on the presence of significant bacteriuria and pyuria on an appropriately collected urine specimen. Significant bacteriuria is characterized by any organisms on a suprapubic specimen, at least 50,000 colony-forming units per milliliter (CFUs/mL) in a catheterized specimen, or at least 100,000 CFU/mL in a clean-catch specimen. *Escherichia coli* is the most common pathogen causing UTI. Other common organisms include *Klebsiella, Proteus, Enterobacter, Citrobacter, Staphylococcus saprophyticus, Enterococcus,* and adenovirus. Pending culture confirmation, urinalysis results can aid in making a presumptive diagnosis and

determining the need to begin antibiotic therapy. Significant pyuria is characterized by at least 10 white blood cells (WBCs) per microliter on an enhanced unspun urinalysis, or 5 WBC per high power field on a centrifuged specimen. Dipstick urinalysis has a specificity of 93%. When it is negative for both nitrite and leukocyte esterase, the negative likelihood ratio (LR) for UTI is 0.2; if either is positive, there is a positive LR of 6, and the LR is 28 if both are positive (24).

Distinguishing between an STI and a UTI based on history, physical examination, and urinalysis can occasionally be challenging, given that there is often an overlap in symptoms (25,26). All adolescent patients presenting with dysuria should have a urine pregnancy test and also be tested for STIs by obtaining cervical swabs for culture. Alternatively, the emergency physician can send nucleic acid amplification testing (NAAT) for *N. gonorrhoeae* and *C. trachomatis* from a self- or physician-obtained cervical swab, vaginal swab, or urine specimen. The sensitivity of NAAT testing depends on the collection method; a urine specimen is more sensitive when obtained at the initiation of urination without cleaning the perineum. Testing and treatment for *Trichomonas vaginalis* in both males and females should be strongly considered based on the community prevalence of disease. Patients with ulcerative lesions on examination should have HSV testing and syphilis serology. Counseling and testing for HIV should also be performed, or a referral made, depending on available resources. If discharge is present, vaginal smears should be sent for yeast and bacterial testing, as well as wet mount preparation if available.

The diagnosis of pinworms can be confirmed with the “scotch tape” test, applying tape to the perianal skin and placing the tape on a glass slide where eggs may be visualized on microscopy.

Routine blood work such as a complete blood count, metabolic panel, or blood culture, is rarely indicated.

KEY TESTING

- Urinalysis and urine culture

- STI testing

ED MANAGEMENT

It is important for the emergency physician to address analgesia for children in pain. The family should be instructed to increase fluid intake to help dilute the urine. Consider prescribing pyridium, a bladder analgesic, for children older than 6 years. Management of dysuria is otherwise guided by the suspected etiology. For children being treated for infection, the first antibiotic dose should be administered in the ED to ensure that oral therapy will be tolerated.

If the urinalysis is positive, children should be empirically started on antibiotic therapy and confirmatory cultures sent to further guide management decisions. Hospitalization with IV antibiotics should be considered for young infants and children with clinical signs of dehydration, vomiting (especially if unable to tolerate fluids and medications orally), ill-appearing children with signs of urosepsis, or concerns about patient compliance or follow-up. Community microbial resistance patterns must be considered when making empiric antibiotic choices (see Chapter 288 for antibiotic recommendations).

The physician must establish ways to ensure follow-up of positive STI tests. Patients must also be informed that their sexual partners need to be tested and treated if needed, and that they should abstain from sexual activity until at least 1 week after they and their partners have completed treatment. Expedited partner therapy, which involves providing prescriptions for patients to give to their sexual partners without first examining them, is an option to consider. Inpatient management with intravenous antibiotics should be considered for patients who have already failed outpatient treatment, children with immunodeficiency, those with a tuboovarian abscess identified on ED evaluation, those unable to tolerate oral fluids or medications, or if there is concern for compliance or the ability to follow-up (see Chapter 184 for details on recommended management).

No specific treatment is indicated for vulvovaginitis. Anticipatory guidance is key for parents, which should include instructions on wiping from front to back, wearing cotton underwear, avoiding tight clothing, and avoiding potential irritants. Barrier emollient creams can be used to reduce irritation. Antibiotics should generally be limited to those with bacteria isolated on culture. A presumptive diagnosis of candida vaginitis can be made based on the presence of a "cottage cheese" like discharge on examination, and treated with a single dose of fluconazole 150 mg. Treatment of symptomatic labial adhesions is with topical estrogen cream twice daily until separation occurs, usually within 1 month.

Pinworms can be treated with a single dose of 100 mg of mebendazole or 400 mg of albendazole. A second dose should be repeated in 2 weeks. All household members over 2 years old should be treated. Anticipatory guidance should be given on washing, bedding, and frequent hand washing to prevent reinfection.

CRITICAL INTERVENTIONS

- All pediatric patients with a suspected infectious cause of their dysuria should be assessed for signs of dehydration or sepsis.

DISPOSITION

All neonates with UTI should be admitted to the hospital for IV antibiotics as per febrile neonate guidelines. Admission should also be considered for children who are ill appearing, have signs of dehydration, or cannot tolerate fluids or medications by mouth. Most other patients can be safely discharged home with appropriate instructions that address supportive care at home, recommendations for follow-up, and indications to return urgently for further care.

Common Pitfalls

- Failure to perform a GU examination in child presenting to the ED with dysuria.
- Making testing and treatment decisions for STI based on sexual history alone, which can be unreliable in the adolescent

population.
- Failure to recognize STI in the adolescent presenting with a complaint of dysuria.
- Failure to recommend treatment for partners when treating patients for STI.
- Failure to diagnose UTI.
- Failure to recognize rare but serious systemic illnesses that may present with dysuria.

CHAPTER 244

Vaginal Bleeding and Discharge in Childhood

Frances Turcotte Benedict, Susan Duffy, and Jonathan H. Valente

CLINICAL PRESENTATION

Vaginal bleeding can present in a wide variety of ways, from scant to copious. Profuse vaginal bleeding in an infant or prepubertal child should raise concern for trauma or abuse, while infants in the first month of life and postpubertal females can have a normal physiologic vaginal discharge called leukorrhea, which is usually clear, odorless, mucous-like, and whitish-yellow. In general, however, any visible vaginal discharge in infants older than 1 month or in prepubertal girls should be considered abnormal.

DIFFERENTIAL DIAGNOSIS

The causes of vaginal bleeding and discharge in children vary depending on patient age (Table 244.1). The withdrawal of maternal estrogen within the first few weeks of life is a common cause of vaginal bleeding or mucus-like bloody spotting in young infants.

TABLE 244.1
Differential Diagnosis for Vaginal Bleeding and Discharge in Infancy and Childhood

Dermatology	Hemangioma
	Lichen sclerosis
	Irritant vulvovaginitis
Endocrine	Neonatal withdrawal bleeding
	Precocious puberty
	Hypothyroidism
	Hyperthyroidism
	Hyperprolactinemia
Infections	Urinary tract infection
	Gonorrhea
	Chlamydia
	Trichomonas
	Group A *Streptococcus*
	Shigella vaginitis
	Candida
Medications	Birth control pills
	Estrogen creams
Neoplasm	Vaginal neoplasm
	Cervical polyp
Trauma	Straddle injury
	Sexual abuse
Other	Urethral prolapse
	Foreign body
	Urate crystals "pink diaper syndrome"

Precocious puberty, the appearance of pubertal development prior to age 8, may present with vaginal bleeding or discharge. Population-based studies have shown that, 27% of African American girls and 7% of White girls showed evidence of secondary sexual characteristics at age 7 (1). In girls less than 3 years of age, rare vaginal tumors such as rhabdomyosarcoma, germ cell tumors, and clear cell adenocarcinoma usually present as vaginal bleeding or spotting (2,3). Urethral prolapse, most commonly found among prepubertal African American females, should also be considered in the differential diagnosis of vaginal bleeding or spotting (4). Exogenous estrogen exposure from birth control pills, creams, and food are other potential cause of vaginal bleeding.

Trauma to the vaginal area or perineum can cause vaginal bleeding, most commonly as a result of straddle injury from falls, bicycle riding, and playing on jungle gyms (5–7). Sexual assault is another potential explanation of vaginal trauma and should be carefully considered if the child is less than 9 months of age and there is evidence of urogenital injury without a history of penetrating trauma, or if there are abnormal genital secretions, and the physical examination findings do not correspond with the history provided (8).

ED EVALUATION

The evaluation should begin with a history that includes questions about urogenital hygiene, trauma, previous history of urinary tract infections, irritation or rashes in the genital region, the presence of estrogen-containing medications in the home, signs of puberty, and any concerns for potential child abuse.

Examination of a prepubertal patient can be performed using two techniques, the frog-leg position or the knee-chest position. Gentle labial traction may need to be used to fully visualize the hymen. In prepubertal children the unestrogenized hymen is delicate and sensitive. To avoid causing pain and bleeding, do not use dry swabs to obtain cultures or specimens. The use of a small feeding tube, medicine dropper, or angiocatheter may be used to irrigate with a few milliliters of saline and then collect specimens at the vaginal introitus. A rectal examination may need to be performed if there is no evidence of blood on inspection of the external genitalia. Most prepubertal and postpubertal nonsexually active females, do not require visualization of the upper vagina and cervix. If there is concern for foreign body or if there is extensive trauma the examination should be completed under general anesthesia. The skin should also be examined for bruising, especially when considering a bleeding disorder or physical abuse.

KEY TESTING

- All menstruating females should have a urine pregnancy test.

ED MANAGEMENT

Reassurance and expectant management is needed for maternal hormonal withdrawal bleeding. For atypical or persistent bleeding with an unclear etiology, examination under anesthesia is recommended (9). If the initial discharge is greenish, bloody, or foul smelling, cultures should be obtained. If cultures are negative, consider Chlamydia testing or formal evaluation for a foreign body (10).

CRITICAL INTERVENTIONS

- Rule out pregnancy in all adolescents who have reached menarche.
- Notify state child protection authorities when there are concerns of child abuse.

DISPOSITION

The majority of patients can be sent home and followed up with their pediatrician. If the cause of their vaginal bleeding or discharge requires them to see a specialist, this follow-up should be arranged prior to discharge. Patients with a large amount of blood loss should be admitted. If there is concern for sexual abuse, the appropriate state child protection authorities should be notified along with a child protection consultant, if available.

Common Pitfalls

- Failure to perform a pregnancy test on children who have reached menarche.
- Failure to consider sexual assault in children with vaginal bleeding and discharge.
- Not arranging follow-up and/or further evaluation since most causes of vaginal bleeding/discharge in children will not be solved in the ED setting.
- Failure to perform a complete genitourinary examination in a child-specific manner.

PART 4 • PEDIATRIC TRAUMA

CHAPTER 245

General Approach to Pediatric Trauma

Rick C. Place and Thom A. Mayer

Unintentional injury is the leading cause of death in the United States for children aged 1 to 19 years of age. Accidents, homicide, and suicide combined are responsible for over 12,000 deaths a year and are, respectively, the three leading causes of death. In children over the age of 10, motor vehicle crashes (MVCs) are by far the leading cause of death, while under 10, drowning and burns or smoke inhalation figure prominently (1). These figures contrast with the first year of life, during which only 4.4% of deaths are related to unintentional injury. During this same time period, there were over 9 million nonfatal injuries in children under 20 years of age (1).

CLINICAL PRESENTATION

Physiologic and Anatomic Differences

Just as the octogenarian is treated differently than the athletic university student, the approach to an injured infant differs greatly from that of the adolescent. While the transition is gradual, the changes are extraordinary. *Pediatric physiology evolves into more adult physiology during the school-age years, between 7 and 9 years of age.* This chapter focuses on the unique issues of the pediatric patient under the age of 7 and assumes an understanding of adult trauma care (Fig. 245.1) (see Chapter 18).

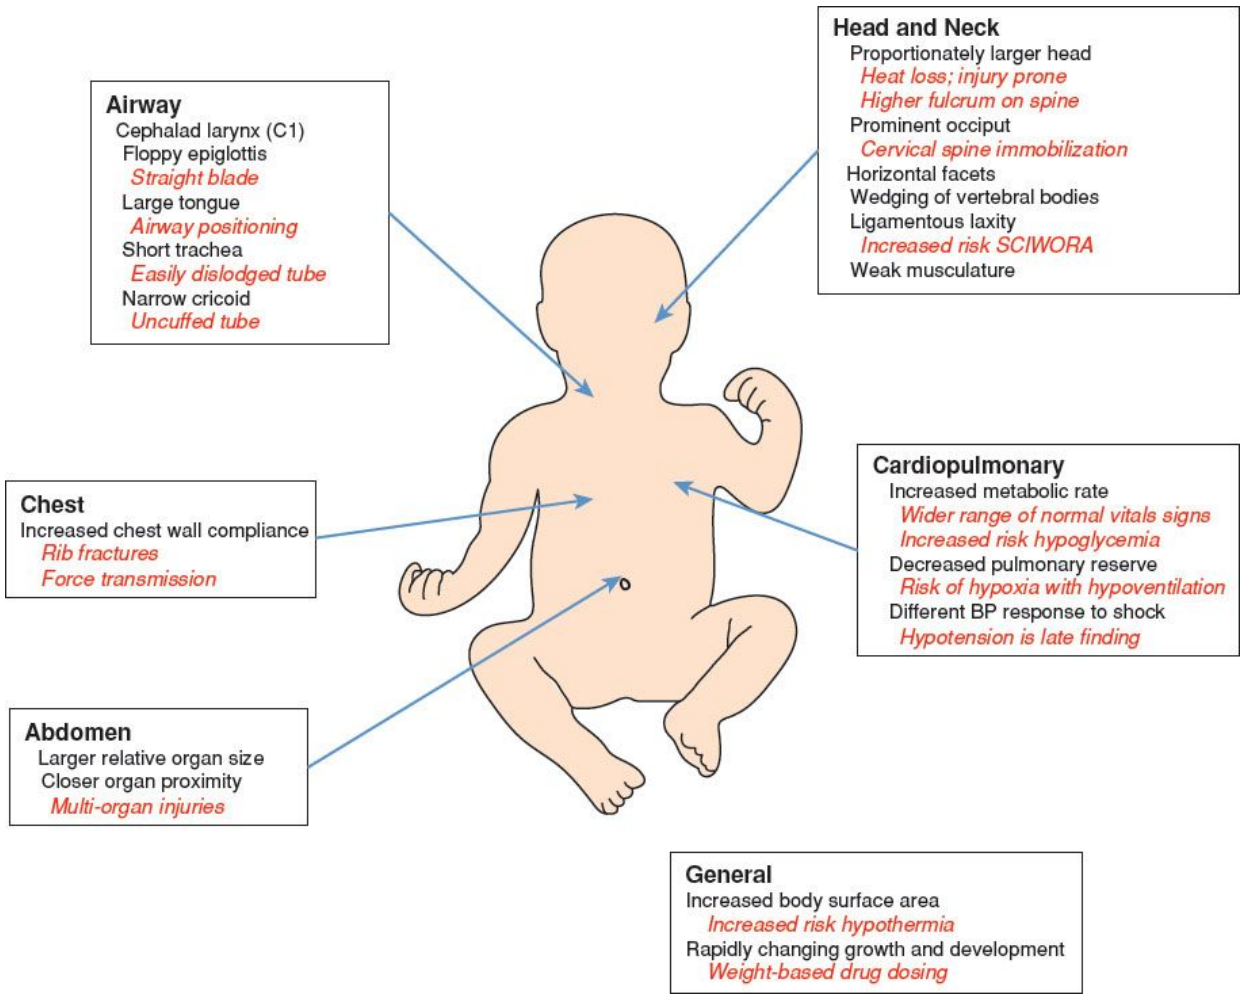

FIGURE 245.1 Pediatric anatomic differences.

One of the most important differences in children is the size of the head relative to the rest of the body. The infant's prominent occiput is comparatively heavy relative to the adult's, comprising 25% of body weight versus 10% in adults. This increased mass, coupled with weaker cervical musculature and hence less overall head control, makes infants and children highly vulnerable to injury. The cranial sutures, open at birth, gradually fuse by 12 to 18 months of age; open bulging fontanels may indicate increased intracranial pressure, but whether this results in meaningful decompression of the injured brain is debatable.

A thin and fragile skull, particularly in the first several months of life, is more liable to fracture with even a minor mechanism. In younger children, particularly those under the age of 2, a boggy

lesion over the site of impact may indicate a cephalohematoma from an underlying skull fracture.

The infant's brain has higher water content, incomplete myelinization, and greater biomechanical vulnerability to impact and shearing injuries relative to adults. This results in a higher rate of diffuse brain injury in children.

Physiologic and anatomic characteristics of the cervical spine, as well as differences in age-related activities, predispose children to different injury patterns. A relatively larger and heavier head results in a fulcrum of flexion at C2/C3, instead of C5/C6 in the fully grown adult. Weaker neck musculature, lax ligaments, anterior wedging of the vertebral bodies, and more-horizontal facets predispose to upper spinal cord injury (SCI). A predominance of upper cervical spine injuries and a greater incidence of SCI without radiographic abnormality (SCIWORA) have been noted in younger children (2,3).

The rate of cervical spine injury in children (approximately 0.7% to 1.6%) is substantially lower than in adults (2.4%). The risk of injury, however, approximately doubles (3.2%) for children involved in MVCs.

The cardiopulmonary response to stress in infants differs from older children and adults. The myocardium is stiffer, less contractile, and less able to generate ventricular wall tension. *The infant heart is therefore more rate dependent, without as much ability to increase stroke volume.* Similar to the heart, pulmonary reserve is more restricted by anatomic structure; minute volume is thus more dependent on rate rather than tidal volume. Children also have reduced functional residual capacity (i.e., oxygen storage) coupled with metabolic demands that are twice those of adults; consequently, desaturation may occur more rapidly and precipitously. *All told, differences in baseline cardiac and respiratory rates, as well as differences in age-related norms, make recognizing compensated shock challenging for providers.*

Certain structural and anatomic differences also place young children at risk for increased morbidity. Their relatively increased body surface area (BSA) increases the risk of hypothermia and leads to necessary modifications of the Rule of Nines chart used for burn

care resuscitation. The less mineralized pediatric rib cage is more likely to bend rather than break, transmitting forces internally without concomitant rib fracture, resulting in higher rates of pulmonary contusion. The pediatric liver and spleen are relatively larger, in closer proximity to one another without surrounding fat and connective tissue, and exist within a less developed, weaker abdominal musculature. This makes these organs, like the lung within the pediatric rib cage, more vulnerable to transmitted blunt forces.

Children's bones are softer and more porous, have increased ligamentous laxity and a greater percentage of unossified cartilage, which improves their ability to absorb blunt metaphyseal impact. However, this leads to a higher rate of epiphyseal injuries in children. While increased laxity serves to protect children from bony cervical spine injury, these same characteristics increase the vulnerability to *cord* injury, demonstrated in its purest form as SCIWORA.

General Approach to the Pediatric Trauma Patient

The fundamental primary survey–secondary survey format of the Advanced Trauma Life Support (ATLS) course remains the most effective and efficient manner of evaluating injured children of all ages.

This structured approach to major trauma is no different from that used in the evaluation of the adult trauma patient, but there are some critical differences. These include (1) the requirement for all team members to agree upon the patient's body weight in order to facilitate error-free weight-based administration of fluids and medications; (2) the need to maintain core body temperature; (3) the need to be especially concerned about the recognition of cervical spine injuries; (4) the need to establish an airway and use appropriate noninvasive ventilation techniques; (5) the need to recognize circulatory stability and shock; (6) the importance of promptly establishing adequate vascular access; and (7) the importance of proper management of pediatric head injury.

PRIMARY SURVEY

Airway and Breathing

The pediatric airway is anatomically immature and different from the airway of older children and adults, particularly in the first 2 years (see Chapter 218). Infants are "belly" breathers, meaning they require full diaphragmatic excursion to produce normal respirations. More-horizontal ribs and a flatter diaphragmatic insertions provide less mechanical advantage. Having said this, most respiratory issues in trauma are related to reduce respiratory effort because of CNS injury rather than respiratory distress from pulmonary pathology.

The highest priority in caring for either adult or pediatric patients with multiple traumatic injuries is ensuring or providing a patent airway with adequate ventilation and oxygenation while protecting the cervical spine. In the severely injured child with an altered level of consciousness and impaired respiratory effort, *the most frequent error is failure to position the airway properly*. In the trauma patient, the jaw thrust is the single most important airway maneuver, pulling the mandible and tongue away from the posterior pharynx. Placing a flattened towel under the shoulders will raise the torso and may help facilitate maneuvers to maintain patency by straightening the airway (Fig. 245.2).

FIGURE 245.2 Pediatric airway. Placing a towel under the shoulders helps better align the airway by raising the torso, optimizing breathing and visualization of the airway.

In pediatric patients with compromised respiratory effort, there is a natural tendency to rush toward endotracheal (ET) intubation, even in the face of suboptimal intubating conditions. This is a common but potentially fatal mistake.

Almost all children can be effectively ventilated by bag-mask ventilation (BMV). As noted above, proper airway positioning is the key to effective BMV. BMV in children is much easier than in adults because of the child's smaller size and more compliant physiology; it is also much easier to generate appropriate tidal volumes and airway pressures. However, it is also easier to produce compromising gastric distention, ventilatory compromise, and unwanted aspiration.

The ubiquitous tendency to overventilate the young child in an emergency situation, both in terms of volume and rate, should be resisted. In the absence of direct pulmonary injury, slow, steady breaths (saying “squeeze . . . release, release”) are all that is required. Furthermore, hyperventilation may be detrimental to the child with traumatic brain injury (TBI), inducing cerebral vasoconstriction and worsening focal or global ischemia.

Indications for emergent intubation of pediatric patients are the same as those for adults: airway obstruction, ineffective respiratory effort or hypoventilation, respiratory distress or hypoxemia, profound neurologic injury (Glasgow Coma Scale [GCS] <8), or altered mental status with combativeness (GCS >8).

A length-based system should be used to select the appropriately sized ETT and intubation equipment. An age-based formula is also commonly used. Choices of induction and paralytic agents are addressed more fully in Chapter 218.

Intubating children in the prehospital environment has been shown to be largely unnecessary and may produce worse outcomes than appropriately performed BMV. The unique anatomy of young children, combined with the rarity of pediatric procedures, results in a situation in which skill development and retention is suboptimal. The rate of unsuccessful intubation and complications is significantly higher than intubation in the emergency department (ED), whereas the benefits remain unproven. The vast majority of pediatric patients can be transported to the ED safely, using BMV or supraglottic devices where BMV is problematic.

In the exceedingly rare instance in which severe orofacial or direct laryngeal injury precludes performing ET intubation, needle cricothyrotomy can be considered. Cricothyrotomy is nearly impossible in infants and young children because the cricothyroid membrane is virtually nonexistent prior to age 4. Because the child can almost always be ventilated by bag-mask techniques, even with severe laryngeal injury, needle cricothyrotomy should be a procedure of last resort. Use of supraglottic airway devices, such as the laryngeal mask airway, may be a viable temporizing measure prior to attempting a surgical airway.

Circulation

Pediatric patients demonstrate more physiologic reserve than adults, and manifestations of hemorrhagic shock may not be obvious for the same degree of blood loss. In addition, persistent hypotension is as likely to be from head injury as uncontrolled hemorrhage, and this should be kept in mind before proceeding with aggressive fluid resuscitation.

As in adults, tachycardia is an early and important response to inadequate tissue perfusion. Infants in particular have a limited ability to increase contractility and must therefore maintain perfusion by increasing heart rate. Unfortunately, as reflected by the wide variation in normal heart rates in Table 245.1, tachycardia is not as specific a sign of blood loss as in adults. Children can greatly accelerate their heart rate from recognized or unrecognized pain, fear, and anxiety, as well as volume loss.

TABLE 245.1
Pediatric Vital Signs

		Infant	1 yr	2 yrs	7 yrs	10 yrs	Adolescent
HR	Upper limit	190	180	160	140	120	100
SBP	Lower limit	70	70 + twice age				90

Shock in children is more likely to present in a compensated fashion, with a normal blood pressure until profound blood loss occurs. A drop in blood pressure is considered more ominous and more likely to represent an advanced state of shock. Once blood pressure has been compromised, meticulous attention and urgent intervention must occur to prevent circulatory collapse.

Clinicians may be at risk of underestimating the presence of shock or the risk of imminent cardiovascular collapse because of a poor sense of what constitutes normal pediatric vital signs. Age-appropriate ranges for pediatric vitals sign should be posted in clear view for *easy* reference in critical circumstances. The formula [70 + (2 times age in years) = systolic blood pressure] for children over the age of 1 is a good

marker to gauge the lower limit of acceptable blood pressure in the trauma setting, where pain and anxiety may increase baseline blood pressures. Any child below this level should be considered hypotensive and in decompensated shock until proven otherwise.

A rapid bolus infusion of 20 cc/kg of crystalloid (normal saline or lactated Ringer solution) should be administered in any child in whom significant blood loss and hemorrhagic shock, compensated or decompensated, are suspected.

The principles of blood replacement in children are similar to those in adults. Once two crystalloid boluses have been administered, blood products should be considered for patients still in hemorrhagic shock or actively bleeding. A single "unit" equivalent of packed red blood cells in the pediatric patient is generally considered to be 10 cc/kg and is expected to raise the hemoglobin 3 gm/dL in the absence of ongoing hemorrhage. In the hemodynamically *stable* pediatric patient who has sustained significant blood loss, no clear consensus exists on what level of blood loss or hemoglobin level mandates transfusion.

There are limits to the reserves of pediatric victims of blunt trauma. Those presenting with severe hypotension (SBP <50) or cardiac arrest have an almost universally dismal outcome, rarely surviving without devastating neurologic disability. The vast majority of these patients die from associated head or SCI, not exsanguinating hemorrhage. The only survivors are likely to be patients without head injury who have a witnessed ED arrest and resuscitation.

Emergency venous access in the young pediatric patient outside specialized pediatric centers is one of the most challenging issues facing the emergency physician. The introduction of intraosseous needles with mechanical insertion devices (e.g., EZ IO™) has dramatically altered the landscape of pediatric venous access. Traditional teaching has been that advanced access methods should be instituted if peripheral access cannot be obtained in three attempts or 90 seconds. However, practically speaking, in the unstable, critically injured child, the patient should be simultaneously prepped for intraosseous insertion as peripheral lines

are attempted. Cannulation of the proximal tibia, distal femur, or humeral head with an intraosseous needle can often be accomplished in seconds. Essentially any pharmacologic agent can be injected through an intraosseous line, including epinephrine, bicarbonate, antibiotics, blood products, phenytoin, and even iodinated computerized tomography (CT) contrast agent (4). Aggressive fluid resuscitation can be optimized by using higher-pressure infusion devices such as pressure bags to maximize flow rates if necessary. In awake and semiconscious patients, pain with infusion can be an issue; after line placement, 0.5 mg/kg of preservative-free lidocaine can be infused to anesthetize the marrow cavity. Pediatric venous access is discussed in detail in Chapter 219.

Neurologic Injury

Providing the "ABCs" is critical not only to the survival but to the functional outcome of the head-injured child. The presence of a significant head injury does not alter the focus on the airway and circulation, but early awareness should heighten the clinician's concern for even brief drops in blood pressure and oxygenation. Hypotension and hypoxia are both critical determinants of neurologic outcome in children with severe TBI.

During the primary survey, the goal is simply to provide an *initial, general* assessment, and the best way to *rapidly* assess overall CNS injury is the patient's level of consciousness. At this stage, the AVPU (Alert, Voice, Pain, Unresponsive) mnemonic is preferred to the Pediatric GCS until there is time for a more in-depth evaluation. By using this brief, simple assessment, the emergency staff can gain a sense of whether significant CNS injury is present.

SECONDARY SURVEY

After the initial survey of the patient's respiratory and circulatory status, the child must be fully undressed for an adequate secondary survey. Although it is important to ensure that the child is undressed rapidly and completely, infants and small children are especially vulnerable to hypothermia, an issue that is easily overlooked in a

busy resuscitation. Temperature is the forgotten vital sign in a critical resuscitation and it should be monitored closely.

Although the purpose is to identify additional injuries that are not immediately life-threatening, one must not neglect closer reassessment of the cardiorespiratory system during the secondary survey. The systematic examination is essentially the same as one would perform in an adult trauma patient, except that some findings may be more subtle in young or frightened children. Two factors may result in deviation from a systematic approach to the secondary survey: (1) a dramatic injury or (2) a frightened, difficult to calm child. Awareness of these issues will prevent injuries from being missed in an otherwise disciplined, systematic, head-to-toe examination.

Head and Brain

The relatively low mortality rate for pediatric blunt trauma rises exponentially in the presence of TBI. TBI is one of the leading causes of traumatic deaths in children, with more than 5,500 deaths per year in the United States. Almost 500,000 ED pediatric visits for head trauma take place every year.

The principles of diagnosis and management of severe TBI (defined as GCS ≤ 8) are similar in children and adults. Diagnosis can usually be made on clinical grounds and management dictated by findings on diagnostic imaging (i.e., CT). The primary injury occurs at the time of impact and is unalterable. However, secondary injury takes place over the ensuing hours to days and is amenable to therapy. Prehospital, ED, and intensive care management of secondary injury may have a profound effect on outcome.

Initially, the major focus should center on prevention of secondary injury from concurrent hypoxia, hypercarbia, and hypotension. Even a relatively brief decrease in cerebral perfusion pressure results in cerebral ischemia and worsened outcomes (5). Ischemic injury is the primary insult in the first 6 to 12 hours, *after which* a second phase of hyperemia and increase in intracranial pressure become increasingly critical. Meticulous attention to blood pressure and oxygenation status is critical in optimizing the outcome in patients with serious

neurologic injury. Hypoxia (oxygen saturation $<90\%$), either from hypoventilation or concomitant pulmonary injury, is associated with increased mortality and must be corrected immediately. Blood pressure should be maintained with normal saline if possible and with vasopressors if necessary. Both the number and duration of hypotensive episodes prior to stabilization have been linked to significant increases in mortality.

Hyperosmolar agents and hyperventilation are the two mainstays of the management of acute brain herniation. Mannitol (0.25 to 1 mg/kg) has been the traditional hyperosmolar agent of choice and has long been used for the management of severe increased intracranial pressure with surprisingly little evidentiary support (5). More recent pediatric studies and the current recommendations of the Brain Trauma Foundation suggest that *the use of hypertonic 3% saline may be superior to mannitol* (5). Acute dosing recommendations for hypertonic 3% saline range from 6.5 to10 cc/kg.

Hyperventilation, which is very common albeit inadvertent in the pediatric resuscitation, reduces $PaCO_2$, inducing vasoconstriction, decreased cerebral blood flow, and decreased intracranial pressure, at the price of decreased brain oxygenation and induced ischemia. Hyperventilation in the setting of severe TBI continues to be used despite a lack of evidence supporting this practice (6). If used acutely as a temporizing measure to control severe increases in ICP and to prevent or limit acute herniation, the $PaCO_2$ should not be driven down below 30 mm Hg and should ideally be kept in the range of 32 to 35 mm Hg. Even a single episode of severe hypocarbia has been shown to produce an increase in mortality (6).

Cervical Spine and Cerebrovascular Injury

A bimodal distribution of cervical spine injury has been noted, with peaks between the ages of 2 to 4 years and 13 to 15 years. Motor vehicle–related injuries (automobile crashes and pedestrian-struck) are responsible for about half of pediatric cervical spine injuries (2). Athletic misadventures cause between one-quarter and one-half of cervical spine injuries and predominantly affect adolescent boys. Not

surprisingly, American football followed by diving are the highest risk activities.

The majority of cervical spine injuries in children under age 8 occur between the occiput and C3 (2). Injury patterns in older children tend to resemble those of adults, with a more equal distribution across all levels. However, even in younger children, fractures of the lower cervical spine (C4 to C7) are possible, and care must be taken to visualize the entire cervical spine when imaging is done. As many as 7% of children with spine injuries are found to have noncontiguous lesions (i.e., at more than one level), reinforcing the recommendation to image the entire spine when a fracture is identified. In addition to fractures, other injuries relatively unique to young children include atlanto-occipital dissociation, atlanto-axial rotary subluxation, and vertebral endplate fractures.

Even in young children with injury to the osseous structures of the cervical spine, traumatic myelopathy (spinal cord injury), is uncommon. Beyond early childhood, thoracic and lumbar SCI is nearly as frequent as traumatic cervical myelopathy. When SCI is diagnosed, the administration of methylprednisolone is expressly discouraged in the most recent guidelines of the American Association of Neurological Surgeons (7). A solid scientific foundation for this practice has never been established in children and recent data strongly suggests that harm outweighs any theoretical benefits of this practice.

SCIWORA, originally described by Pang in 1982, refers to the presence of SCI in the absence of fracture noted on conventional radiography (plain radiography and CT imaging). Ligamentous laxity of the pediatric spine allows for excessive movement and recoil of the spinal column without fracture. SCIWORA can occur at any level but is more common in the thoracic and cervical spine. Most studies report that younger children are more likely to manifest SCIWORA than older children, and when they do, it is likely to be more rostral and more severe. SCIWORA is a well-recognized phenomenon, but it is quite rare, found in less than 15% of pediatric patients with traumatic myelopathy. Neurologic signs or symptoms without a clear

explanation on conventional imaging should be further investigated with magnetic resonance neuroimaging (MRI).

Blunt carotid and vertebral cerebrovascular injuries do occur in children, and risk factors mimic those in adults (8). Vertebral artery injuries occur almost exclusively with cervical spine injuries, particularly C1 through C3. Carotid injuries, resulting from severe cervical hyperextension or rotation, are more strongly associated with major thoracic trauma. Other, lesser risk factors include basilar skull fracture and unexplained neurologic deficit or unexplained GCS <8 (i.e., normal head CT) (8).

When cerebrovascular injury is present, subsequent stroke risk is high and the window of opportunity that exists *before* neurologic signs and symptoms ensue should not be ignored. While the incidence in pediatric blunt trauma may be under 1%, the use of recognized risk factors may produce a yield above 20% (8). Any patient undergoing a thoracic CT scan or found to have a cervical spine fracture should be strongly considered for cerebrovascular CT angiography.

Thoracic Trauma

Severe chest trauma is second only to TBI as a cause of death in pediatric trauma patients. About 10% of children with blunt torso trauma are ultimately diagnosed with a thoracic injury, about half of whom have more than one finding (9). Major chest trauma is a marker for severe blunt force impact, and the presence of chest trauma in the setting of polytrauma is associated with a 20-fold increase in mortality. Severe thoracic trauma is also associated with other major injuries such as cerebrovascular, head, and cervical spine injury.

Abnormalities on the chest examination are reasonably sensitive for thoracic injury. However, increased chest wall compliance means that significant internal injury may exist in the absence of visible external injury (9). The majority of internal thoracic injuries in children are not accompanied by rib fracture. When present, fractures of more than one rib is associated with a significantly greater mortality rate (42% vs. 18%).

Predictors that have been associated with intrathoracic injury include (1) hypotension, (2) abnormal chest examination or chest auscultation, (3) altered mental status, and (4) femur fracture (9).

Hemothorax, pneumothorax, pulmonary contusion, and rib fractures are the most commonly encountered pediatric chest injuries (9). Fortunately, other more life-threatening tracheobronchial, esophageal, cardiac, and thoracic vascular injuries are extremely uncommon (10).

Pneumothorax is more common with major chest trauma in children than in adults and is associated with a significant increase in mortality. Other concurrent intra- or extrathoracic injuries are frequently present and should be sought after. While the presence of pneumomediastinum heightens concern for other major intrathoracic injuries, it generally has little clinical significance. Both simple pneumothorax and hemothorax can generally be managed with an appropriately sized tube thoracostomy.

Vascular injuries are the most lethal thoracic injuries but fortunately are exceedingly rare in children (10). Traumatic aortic injury is less common in children than adults and is more often discovered in ambulatory or bicycling children who are struck by a moving vehicle.

Cardiac contusion in blunt pediatric trauma is diagnosed by a combination of elevated cardiac enzymes, the presence of arrhythmias (usually noted in the ED) and depressed cardiac output on echocardiogram. As in adults, blunt cardiac injury occurs in the context of multisystem trauma, and isolated cardiac injury is rare.

Abdomen

After the head, the abdomen is the most commonly injured body area from MVCs. Of those who are restrained by seatbelts, children in the age range of 4 to 8 years who transition too early from child to adult belts are the most likely to be injured. The proper restraint is a booster seat, which provides optimal placement of the seat belt and allows the belt to sit on the pelvis. The pelvis is able to withstand greater force without injury than the viscera of the mid-abdomen.

The most valuable part of the pediatric abdominal examination is palpation. Verbal children should be asked if and where they hurt and the examination is then begun away from that site. Younger children are frequently frightened, and verbal responses to leading questions regarding either the presence or absence of pain should be interpreted cautiously; unsolicited complaints of pain should be taken very seriously. Serial examination of the abdomen may be necessary for accurate assessment and may reveal significant findings that were missed on the initial examination.

The significance of a seat belt sign or other visible evidence of abdominal trauma has been questioned. A recent study of 1,963 children with blunt torso trauma and visible evidence of abdominal trauma highlights the importance of this finding: 112 (5.7%) required active medical or surgical intervention (11). In the context of a seat belt sign, the presence of free fluid on abdominal CT predicts operative intervention (12). Chance fractures of the lumbar spine, less commonly seen with the near-universal use of three-point seat belts, can still occasionally be seen in inappropriately restrained children and may be associated with hollow viscous injury.

Each intra-abdominal organ has a unique anatomy and physiology that necessitates a particular approach. Solid organ injuries of the liver, spleen, or kidney in children have been managed nonoperatively since the 1980s with a success rate of over 90%, regardless of age (see Chapter 251).

Pelvic Fractures

Pediatric pelvic fractures are uncommon and are the result of high impact injuries, most notably pedestrians struck by vehicle and MVCs. Skeletal immaturity (prior to age 14 in boys and age 12 in girls) is protective and leads to less severe fracture patterns that are amenable to more conservative management. Severe pelvic hemorrhage and the need for blood transfusion is less common in children than adults, and any increase in mortality is almost exclusively related to concomitant injuries.

Torode and Zieg grade 4 injuries (unstable ring fractures usually involving the posterior elements) are very rare, but recent work

suggests that more aggressive surgical management results in improved outcomes. While bony injuries are often very forgiving in children, the pelvis does not undergo significant remodeling once union occurs, emphasizing the importance of establishing anatomic reduction and joint congruity. Pelvic asymmetry and leg-length discrepancy (from premature sacroiliac epiphyseal closure), scoliosis, chronic low back and sacroiliac pain, and hip dysplasia are all long-term complications of suboptimal management.

Injuries with Delayed Diagnosis

The rate of missed injuries in pediatric trauma patients has been reported to range from 1% to 19% but probably lies at the lower end of this range. Children with a delayed diagnosis are more likely to initially present with altered mental status, require emergent intubation, and have higher severity scores and more identified injuries. However, as many as 50% of delayed diagnoses do occur in patients with a low ISS score (<4) and an initial diagnosis of a single injury.

Fractures comprise the majority of delayed diagnoses, and most missed injuries are of relatively low consequence. However, delayed diagnosis of intra-abdominal injuries can result in significant morbidity. Gastrointestinal injuries are, not surprisingly, the most commonly missed intra-abdominal injury; thus, vigilance for these injuries must be maintained (11,13).

Pain Management

Effective pain management is a particular problem in young patients. This is probably due to a combination of inadequate experience in managing significant pain in pediatric patients, fear of overdosing young infants and children, and failure to fully appreciate the extent of anxiety and discomfort in younger patients. Nonverbal children are especially difficult to assess, both in terms of their degree of pain and in their response to analgesia. The inability to fully recognize pain in young children offers a subconscious excuse to undertreat these patients.

One additional barrier to effective pain management is the difficulty or discomfort of placing an intravenous line, particularly if it is solely for narcotic administration. A recent and effective solution to this problem is the administration of intranasal fentanyl. Typical doses are 1.5 to 2 μg/kg, with a maximum of 100 μg due to volume constraints. Nitrous oxide can also provide relief and can be used early on, prior to placement of an intravenous line.

Parental Presence and Family-Centered Care

Many medical providers, particularly those who provide pediatric care on a less regular basis, would prefer that parents *not* be present during a major resuscitation, either because of concerns regarding family interference, perceived psychological distress to the family, or increased stress on providers. Parents, however, would clearly like the option to choose whether to be present or not, and this choice is supported by American Academy of Pediatrics policy. Recent evidence supporting this policy demonstrates that family presence does not negatively affect the efficiency of pediatric trauma or medical resuscitation (see Chapter 293).

ED EVALUATION

Laboratory Studies

Laboratory studies should be ordered on patients in shock, with an altered level of consciousness, or with evidence of multisystem injury. At a minimum, these should include immediate bedside glucose testing, hemoglobin, electrolyte panel, and type and screen or crossmatch. This can be achieved with a single iSTAT analysis and type and hold.

Additional studies may be indicated depending on the clinical scenario and local institutional approach. Aspartate transaminase (AST) and/or alanine transaminase (ALT) are incorporated into diagnostic imaging protocols at some institutions (13,14). Although liver enzymes may not be a routine part of the trauma evaluation in all centers, they are felt to be useful in identifying the presence of occult intra-abdominal injury when the abdominal examination is

equivocal, for example, in patients with altered mental status or head injury, in toddlers and young children, and in infants in whom nonaccidental trauma is suspected (11). Coagulation studies should be ordered in patients with severe TBI, where the incidence of coagulopathy may be as high as 40%. Urine pregnancy testing should be routinely performed in adolescent girls over the age of 12.

Urinalysis should be examined for gross hematuria when available (13). Many pediatric studies suggest using a low threshold of microscopic hematuria as a driver for further imaging. However, isolated microscopic hematuria in the absence of another indication for abdominal imaging is not strongly associated with abnormal findings on CT (13). Interestingly, the presence of hematuria is less suggestive of genitourinary injury than to other intra-abdominal organs.

DIAGNOSTIC IMAGING

CT and Radiation Risk

The value of CT to diagnose traumatic injury in adults is well established. However, growing children are more susceptible to the effects of ionizing radiation than adults and have a longer period of time to develop a malignancy after exposure. It is estimated that the lifetime risk of developing cancer from an abdominal or head CT performed before the age of 10 is between 1 in 1,000 and 1 in 1,500. Therefore, thoughtful risk assessment should be employed to decide which children, if any, need CT imaging.

A cranial CT results in an average exposure of about 2 mSv, more than 100 times that of a plain chest x-ray (0.02 mSv) (Fig. 245.3). For comparison, a neck CT exposes the patient to 2 to 3 mSv, a chest CT 3 to 7 mSv, a CT of the abdomen and pelvis up to 14 mSv, and a “pan-scan” 21 mSv. In one study, the mean radiation exposure for admitted pediatric trauma patients was 17.9 mSv and 18.4 mSv for those who were discharged (15). These doses fall well within the range associated with an increased risk for leukemia, thyroid, and solid cancers.

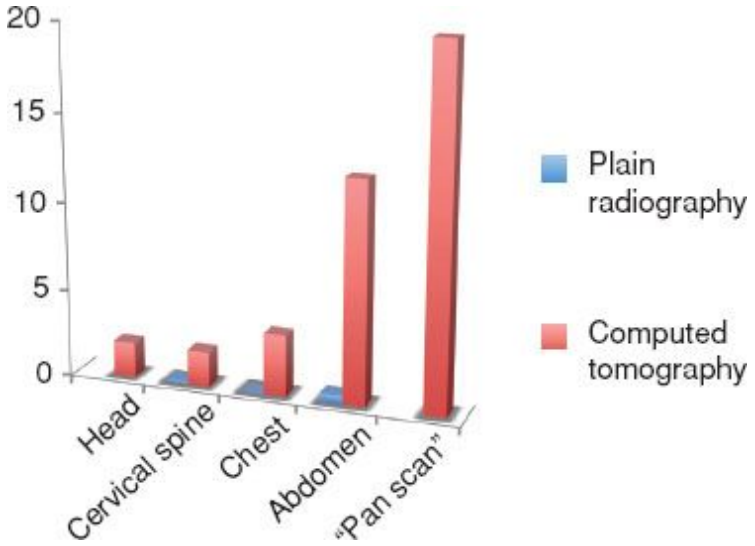

FIGURE 245.3 Ionizing radiation exposure by diagnostic study (mSv).

In adults, CT is routinely obtained to look for blunt aortic injury and cervical spine fracture, and its utility is well documented. The diagnostic yield for CT scanning is lower in children and its utility relative to plain radiography has not been convincingly demonstrated (15–18). Yet radiation exposure in pediatric trauma has become more indiscriminate, with a high percentage of scans being done in patients with relatively low acuity (ISS 6) and few positive findings (19%) (11,16). A composite of pediatric decision rules to determine the need for imaging is shown in Table 245.2.

TABLE 245.2
Risk Factors for Identifying Injury

Head

Altered mental status (*determined by parent*)

GCS ≤ 14 (*determined by MD*)

Palpable skull fracture

Vomiting

Loss of consciousness (*not transient*)

Severe headache

Cervical Spine

Altered mental status

Focal neurologic findings

Abdominal

Seat belt sign

Abdominal pain/tenderness

Significant thoracic trauma

Femur fracture

Unexplained hypotension

Altered mental status

Head Injury

That children with obvious neurologic findings or unequivocally altered mental status after head trauma need an immediate head CT is not controversial. A major dilemma in pediatric emergency medicine, however, is the approach to diagnostic imaging of the child with minor head trauma and normal or near-normal mental status (i.e., GCS 13–15) (Table 245.2). This issue is particularly challenging in preverbal children (see Chapter 246, Major Head Injury; and Chapter 247, Minor Head Injury).

It should be remembered that head injury decision rules generally do not identify which children *require* CT imaging. Rather, they identify a low-risk population that *does not require* neuroimaging. The PECARN rule splits the non-low-risk population into those who require a CT and those who can be managed alternatively with clinical observation. Clinical judgment is still necessary to prevent unnecessary imaging.

Cervical Spine Injury

Cervical spine injury in children is distinctly uncommon and is noted in less than 1% of blunt trauma patients, compared with 2.4% of adult blunt trauma patients. Because the numbers of young children in major validation studies are low, guidelines such as NEXUS, and the Canadian Cervical Spine rules cannot be comfortably applied to young children. Most pediatric decision rules are derived from case series.

There are no clear pediatric guidelines for clinical clearance of the pediatric cervical spine. For this reason, imaging of pediatric trauma patients tends to be quite liberal, particularly in nonpediatric centers (16). In a study of radiation exposure in pediatric trauma, of patients getting at least one CT scan, 97% of patients had a head CT (of which 24% were positive) and 62% had a neck CT (of which only 3% were positive) (16). The extent of imaging found in many studies probably reflects the widespread belief, especially outside of pediatric trauma centers, that young children are difficult if not impossible to clear clinically (17). Recent work has begun to firmly establish that cervical spine imaging is not necessary in all patients, and that physicians can identify low-risk pediatric populations that can be cleared clinically (19).

Findings associated with a risk of intracranial injury include (1) altered mental status, (2) focal neurologic findings, (3) neck pain, (4) restricted range of motion, (5) thoracic trauma, and (6) mechanism predisposing to cervical spine injury such as diving or high-risk MVC (19).

The results of these studies *do not* imply that all children who fail to fall into the “low-risk” group require diagnostic imaging. Patients who do not fall into these low-risk parameters require heightened diagnostic judgment, not an automatic default to the radiology department.

Even though adult practice has steadily moved toward CT as the imaging study of choice, such a consensus does not exist in the pediatric literature. Evidence of equal benefit is lacking, and plain radiography appears to be more sensitive in children. The Canadian

Consensus and other guidelines suggest that there is still a primary role for plain radiography as the initial assessment tool in children (3,17). CT should be reserved for situations in which there is diagnostic uncertainty for clinical or radiographic reasons. Pediatric patients with an "unreliable" clinical examination should be treated cautiously and conservatively, but the simple fact that young children are preverbal does not automatically categorize their examination as "unreliable" (17) (see Chapter 249).

Thoracic Trauma

Chest radiography is a sensitive screening test for significant intrathoracic injury in children, particularly for those that require immediate surgical intervention (20). Other studies have noted that as many as one-third of thoracic injuries identified on CT are missed on plain chest film, the vast majority being pulmonary contusions, small pneumothoraces, and nondisplaced rib fractures (9,10,18). With the increase in "pan-scanning," the use of routine chest CT in children, with or without preceding chest x-ray, has greatly increased, without an apparent increase in detection of significant pathology. One study of 353 pediatric patients who had chest CT as part of their evaluation found no life-threatening injuries that were not suggested by plain chest x-ray, even as the use of chest CT doubled during the study period (20).

While CT has clearly been shown to be more sensitive than supine chest x-ray in identifying thoracic injuries, the clinical significance of those additional discoveries is questionable and management is rarely altered (10,18,20). Furthermore, evidence suggests that the great majority of significant intrathoracic injuries are located in the lower thoracic cavity and can actually be identified on abdominopelvic CT (9,10).

Plain chest films therefore remain the imaging study of first choice in pediatric chest trauma. CT should be reserved for patients with an abnormal chest x-ray or in whom major or potential life-threatening injuries (e.g., vascular, esophageal, or bronchopleural) are suspected, or for further assessment of major bony injury such as vertebral or sternal fractures (10).

Abdominal Trauma

Abdominal CT has become the near-gold standard for the identification of intra-abdominal injury. However, identifying which child needs intra-abdominal imaging remains a challenge. As few as 10% of CT scans performed for blunt abdominal trauma are diagnostic of injury (13). In an attempt to limit the number of unnecessary CT scans of the abdomen and pelvis, a number of decision rules (as opposed to guidelines) have been created over the past decade (13,14). These rules rely on combinations of physical examination findings and laboratory studies. While published pediatric algorithms provide some guidance as to what constitutes a low-risk group, the specificity and positive predictive value of these prediction rules is poor and if strictly applied, they would result in overimaging. In contrast to the application of cervical spine guidelines, there is a much greater need to combine clinical judgment with currently available evidence (13).

A recursive partitioning analysis of 1,095 pediatric trauma patients with blunt torso trauma, with a 10% rate of intra-abdominal injury, found three physical findings that were associated with intra-abdominal injury—hypotension, abdominal tenderness, and femur fracture. There were three laboratory findings as well—
elevated liver transaminases, microscopic hematuria (>5 RBC/hpf), and low hematocrit. More recently, a larger multi-center study of more than 12,000 pediatric victims of blunt torso trauma which looked only at historical and physical examination variables found that the most important predictors of intra-abdominal injury were, in decreasing order of importance, physical evidence of trauma to the abdomen, altered mental status (GCS ≤ 13), abdominal tenderness, physical evidence of trauma to the thoracic wall, complaint of abdominal pain, decreased breath sounds, and vomiting (11).

For clinicians relying primarily on clinical findings for decision making, the presence of visible abdominal trauma, abdominal tenderness, the presence of unexplained hypotension, and a low GCS (i.e., unreliable examination) are most highly associated with the need for intervention (11,13,14). Thoracic trauma and femur fracture

both serve as markers for major impact force and should prompt strong consideration of abdominal imaging.

The abdominal CT occasionally demonstrates the presence of free fluid in the absence of identifiable organ injury. A*ny* free fluid is suspicious for injury, but its mere presence does not mandate laparotomy and should be addressed with serial abdominal examinations (12). The amount of free fluid is clearly associated with the risk of intestinal injury; a significant probability of intestinal injury is found with large amounts of free fluid, whereas smaller amounts are more likely secondary to mesenteric and other injuries.

The decision to take a child to the operating room is largely a clinical one, based on physiologic parameters, either at presentation or over the ensuing period of observation. Patients taken to the operating room based solely on CT findings have a significantly lower rate of therapeutic laparotomy than patients taken for clinical reasons.

Pelvic and Extremity Trauma

The need for routine conventional pelvic radiographs is limited. Pediatric patients experience less than half the proportion of pelvic fractures of adults with similar mechanisms of injury. However, children with pelvic fractures have the same incidence of intra-abdominal injury as adults (around 15%), and thus serious consideration of abdominal CT imaging is warranted. Fortunately, the incidence of life-threatening bleeding from these fractures appears to be low in the pediatric population. It should be noted that, compared with CT imaging, conventional radiography is less sensitive than in adults, only 54% sensitive in one study.

Ultrasound FAST Examination

In experienced hands, the Focused Assessment of Sonography in Trauma (FAST) examination can be very helpful in identifying unstable trauma patients who need immediate operative intervention. It can be performed rapidly and without delay in the

resuscitation bay while other life-saving interventions are simultaneously taking place.

An important limitation of the FAST examination in pediatric patients with blunt abdominal trauma is that, compared with CT scanning, it may not be sensitive enough to identify all clinically significant hemoperitoneum (21). FAST examination is even less sensitive for identifying intra-abdominal organ injury when there is little or no associated free fluid (21). Therefore, unless unstable, patients in whom there is clinical concern for intra-abdominal injury should advance to CT imaging regardless of FAST scan results. Furthermore, while the presence of free fluid on FAST examination is very suspicious for injury, it is not an unequivocal indication for operative intervention; most pediatric patients with intra-abdominal injury will be managed medically (21).

In summary, the FAST examination is most useful in identifying which *unstable* pediatric trauma patient should receive immediate operative intervention. A negative FAST examination should not be relied upon for decision making in stable patients and CT remains the imaging modality of choice.

Disposition

In many areas of the country, pediatric victims of serious traumatic injury are preferentially directed toward established trauma centers with expertise in pediatric patients or to pediatric trauma centers. These centers provide evidenced-based care based on the latest protocols and guidelines. Trauma care is a team effort and in most centers it is a collaborative effort between emergency medicine (or pediatric emergency medicine) and trauma surgery.

Activation of the trauma team is dependent upon triage protocols that are designed to provide timely, optimal care to seriously injured patients without delivering expensive, inefficient care to those who do not need it.

The use of anatomic and physiologic criteria seems to be significantly more effective than traditional consideration of mechanism of injury for identifying the need for high resource utilization (22). Such an approach maintains similar sensitivity for

identifying traumatic injuries while reducing overactivation of strained resources.

The American College of Surgeons has mandated six triage criteria (ACS-6) for the highest level of activation for both adult and pediatric trauma centers:

- age-specific hypotension
- respiratory compromise
- provision of blood prior to transfer from another hospital
- gunshot wound to chest, abdomen, or neck
- GCS <8 or reduction of GCS by two or more from initial assessment

While these are adult criteria, they have been shown to be reasonably effective in triaging pediatric trauma patients. The addition of age-defined tachycardia and findings that indicate poor perfusion, and the need for prehospital fluid resuscitation with greater than 40 cc/kg crystalloid, improves the sensitivity of these criteria in children, with only a modest decrease in specificity.

Dedicated pediatric trauma centers, and adult trauma centers with added qualifications in pediatric trauma care, have increasingly been recognized to provide care that is superior to that available at adult level 1 or level 2 trauma centers or at general EDs. Mortality differences are difficult to demonstrate because of the low rate of traumatic death in children, but a focus on morbidity as revealed through "processes of care" have revealed stark differences (23). Adult surgeons managing trauma in the community setting are significantly more likely to intervene operatively than pediatric surgeons at a pediatric specialty center. These concerns go beyond just the potentially limited pediatric skills of the immediate providers but address the breadth of the support services for the critically injured pediatric patient: surgery, anesthesia, orthopedics, and especially pediatric intensive care services (23).

Ideally, this would mean that pediatric trauma patients are guided toward centers with the greatest pediatric expertise, balanced by the extent and threat of the injury, risk, inconvenience, distance from the specialized center, and resource expenditure. That having been said, access to trauma centers is not universal, particularly in the first

hours. The great majority of pediatric patients continue to be evaluated and treated, at least in the initial phase of their illness, at nonspecialized, general EDs. Children with major traumatic injuries should be transferred to a designated pediatric trauma center, or adult trauma center with pediatric expertise, where such designated regional referral centers exist. Ideally, established written protocols for interfacility should exist prior to transfer. Such an agreement would define reciprocal responsibilities, process for selecting the most appropriate transport service, and clinical indications for transfer.

Common Pitfalls

- Failure to appreciate age-related norms and the recognition of compensated shock in children.
- Failure to avoid even brief periods of hypotension or hypoxia in children with severe TBI.
- Failure to provide appropriate analgesia to the distressed child.
- Lack of familiarity with pediatric-specific criteria for the management of pediatric trauma patients.
- Overreliance on CT imaging in the assessment of pediatric trauma patients.

CHAPTER 246

Severe Head Trauma and Traumatic Brain Injury in Children

Josh Easter and Rick Place

Traumatic brain injury (TBI) is a leading cause of death and disability in the pediatric population. Roughly 60,000 children aged 0 to 19 years are hospitalized every year for TBI. Of these, about 10%, or 6,000, die of their injuries; well over half of them are older teenagers (11).

In very young children, injury is primarily due to falls. In adolescents TBI is the result of falls, motor vehicle accidents, and impact by an object such as a motor vehicle (11). Such age-related differences have significant implications in terms of specific injury patterns and prognosis.

Rapid identification and aggressive management of children with severe TBI (sTBI) improves outcomes (3). A retrospective review of pediatric deaths following TBI classified nearly one-third as potentially preventable with early intervention (32).

CLINICAL PRESENTATION

The infant's brain differs from its mature counterpart in that the higher water content and incomplete myelinization make the young child more vulnerable to diffuse brain injury. The child's head is relatively larger and heavier in proportion to the body, creating a higher fulcrum of rotation in the neck, which explains the greater propensity for high cervical spine injuries. The calvarium is more

fragile in very young infants and more likely to fracture with minor impacts. While sutures may remain open until about 18 months of age, it is unclear whether they are effective in dissipating the force of an impact or in providing room for expansion in case of increased intracranial pressure.

The possibility of intracranial bleeding should be considered in any child with a significant head injury. The skull in young children is relatively flexible, and intracranial hemorrhage may be present in the absence of skull fracture (18,20).

Epidural Hemorrhage

Epidural hematomas are uncommon in infancy, as the dura is still firmly attached to the skull. In toddlers and older children, skull fractures arising from direct blows may lacerate meningeal arteries, the great majority of which are temporal/temporoparietal in location (20). Epidural hematoma may be venous in origin, however, arising from rotational injuries that damage sinus emissary veins. The mechanism may frequently be relatively minor; falls from less than 5 ft are the most common cause of epidural bleeds in young children and infants (34).

The classic presentation is a brief loss of consciousness followed by a lucid interval and then rapid deterioration as arterial blood accumulates to create a mass effect. The presentation varies and some children may have a relatively normal neurologic examination at the time of presentation (20). However, most exhibit headache, vomiting, or lethargy.

Epidural hematomas appear as lentiform (biconvex) hyperdensities on CT imaging, displacing the brain away from the skull (Fig. 246.1). As the dura usually remains firmly attached to the sutures, the hematoma generally does not cross suture lines (18). Areas of mixed hyperdensity and hypodensity, known as the “swirl sign,” suggest active bleeding at the time of the scan and typically requires immediate neurosurgical evacuation.

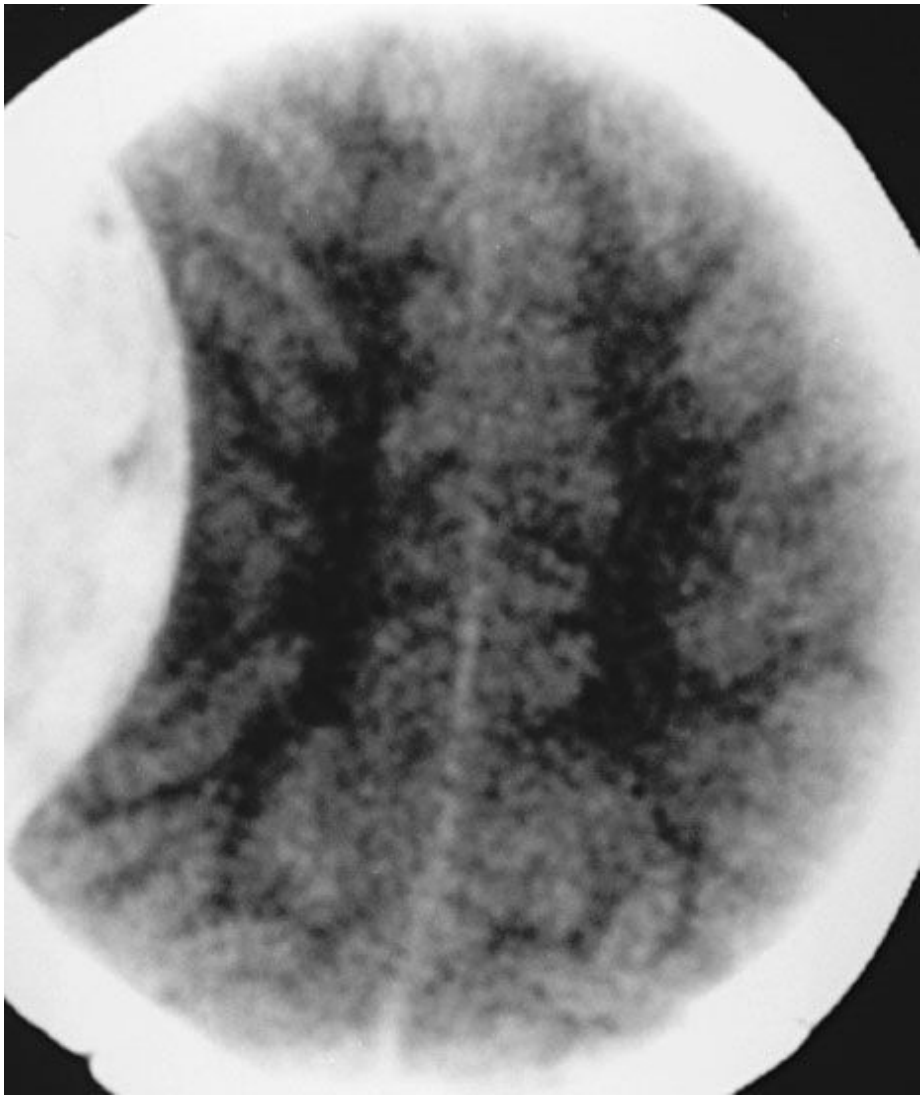

FIGURE 246.1 Epidural hematoma. This 8-year-old boy presented after a sledding accident. He had no loss of consciousness but complained of headache and vomiting. A head computed tomography scan shows the classic biconvex hyperdensity of an epidural hematoma. He proceeded to the operating room, where a large mass of clotted blood was removed.

The vast majority of children with epidural hematomas require operative intervention; neurosurgical consultation should be obtained emergently, regardless of the current mental status (20,34). Although conservative management has been advocated for patients with a small epidural hematoma (e.g., <1 cm) and a GCS of 15, the

majority of these patients ultimately proceed to surgery (20). Delay of neurosurgical intervention is the only factor that has been associated with increased mortality; even patients with a dilated ("blown") pupil are likely to survive and do well if operated on within 90 minutes. Outcomes are generally good and are largely dependent upon condition at presentation; children who have an initial normal neurologic examination uniformly do well (20).

Subdural Hemorrhage

Subdural hemorrhage is generally caused by an impact that produces severe acceleration/deceleration or rotational forces. Blood accumulates because of tearing of the bridging veins between the dura and the arachnoid membrane (Table 246.1). Injuries to cerebral cortical arterioles can also lead to arterial hemorrhage into the subdural space. Acute subdural hemorrhages (less than 72 hours old) commonly appear as homogenous, hyperdense, concave or crescent-shaped lesions on CT imaging. Unlike epidural bleeds, subdural hematomas are not limited by dural suture attachments and may cross sutures lines.

TABLE 246.1
Intracranial Lesions in Children

	Epidural Hemorrhage	Subdural Hemorrhage
Pathophysiology	middle meningeal artery injury	Bridging vein injury
Mechanism	Falls, MVCs	Nonaccidental trauma, MVCs
Presentation	Early	Late
Diagnosis (CT)	Biconvex hyperdensity, does not cross suture lines	Concave hyperdensity, crosses suture lines
Management	Medical > Surgery	Medical > Surgery
Associated Injury	80% skull fracture	60% concomitant brain injury
Mortality	5%	15%
Morbidity	15%	5%

MVC, motor vehicle collision.

Subdural hemorrhages are most common in infants and are usually the result of nonaccidental trauma (31). Bleeding that appears chronic (hypodense on CT imaging), is seen in the interhemispheric space or posterior fossa, or is noted at multiple sites, is highly suggestive of nonaccidental trauma. Beyond infancy, subdural hematomas are usually frontal and parietotemporal and are associated with a significant direct blow to the head (18). Association with other brain injuries is significantly more common than with epidural hematomas and the prognosis tends to be worse.

Children with a midline shift or mass effect require urgent operative management. Those with severe alteration in neurologic status often have concomitant brain injuries (e.g., diffuse axonal injury, cerebral contusions) and are sometimes managed nonoperatively.

Severe TBI results in both primary and secondary injuries. Primary brain injury, such as hematoma and shear injury, is a direct result of the precipitating event. Secondary injuries arise minutes to hours to days following the initial insult and are modifiable by therapeutic intervention. Secondary brain injury is exacerbated by hypoxemia, hypotension, elevated intracranial pressure (ICP), and seizure activity. Even brief episodes of hypotension or hypoxia after TBI are associated with worse outcomes (33). The primary goal of emergency management is to minimize secondary injury with timely intervention to optimize blood pressure, oxygenation, ICP, and cerebral blood flow.

Acutely *elevated* ICP, resulting from focal mass effect (e.g., epidural hematoma) or more global injury (e.g., diffuse axonal injury) may have deleterious effects on cerebral perfusion and the delivery of critical metabolic substrates, including oxygen and glucose, to the CNS (12). Cerebral blood flow is directly related to cerebral perfusion pressure (CPP), which is calculated as the mean arterial pressure *minus* the intracranial pressure (CPP = MAP − ICP). The ICP is measured most accurately by an intracranial pressure monitor.

In adults, the critical threshold for CPP lies in the range of 50 to 70 mm Hg, but in young children, it may be as low as 40 mm Hg, with a 100% mortality rate below this threshold reported in one

retrospective study (2,10,12,27). Above this level, however, a threshold beyond which active maintenance of CPP contributes to improved outcomes has not been well defined (2,3). It is likely that there are different CPP thresholds at different ages (25,27).

Hypotension (variously defined as a MAP or systolic pressure below the fifth percentile) can reduce CPP, leading to cerebral hypoxia and exacerbating secondary injury (1,33). Even a single episode of hypotension harbors a risk for poor functional outcome after sTBI in children, particularly in the first 6 hours post injury. Attention to this critical parameter has been suboptimal. In a recent study of children with sTBI presenting to a level 1 trauma center, 39% of children had documented hypotension, but it was addressed in less than half and the outcome was worse in those patients.

Increases in ICP can also be associated with cerebral hypoperfusion, regardless of the blood pressure. Extra-axial blood collections, vasogenic edema secondary to neuronal cell death, and loss of vascular autoregulation can lead to increased ICP. Pediatric studies have consistently demonstrated that elevations of ICP >20 mm Hg are associated with significantly increased adverse neurologic outcomes.

Severe TBI is defined as a Glasgow Coma Scale (GCS) of ≤ 8, moderate TBI as a GCS of 9 to 13, and mild TBI as a GCS of 14 to 15. The Pediatric GCS should be used for young children. Providers must reassess children frequently to promptly detect increased ICP; a child who arrives with a GCS suggestive of mild TBI may rapidly deteriorate and require emergent intervention.

Herniation occurs when brain parenchyma is displaced due to intracranial mass effect from intracranial hematoma or malignant cerebral edema. The four common cerebral herniation syndromes transtentorial, tonsillar, central, and subfalcine, are described in Table 246.2. Acute signs of herniation include anisocoria (pupillary asymmetry greater than 1 mm), pupillary dilatation, nonreactive pupils (less than 1 mm reactivity), unilateral weakness, extensor posturing, Cheyne–Stokes breathing (rapid, deep breathing alternating with apnea), and Cushing's triad (hypertension, bradycardia, and irregular respirations). Since few children manifest

the stereotyped *sequence* of events as classically described, any signs of herniation are ominous and must be addressed emergently. Progressive herniation results in neurologic devastation or ultimately death.

TABLE 246.2
Common Cerebral Herniation Syndromes

	Transtentorial	Tonsillar	Central	Subfalcine
Location	Temporal lobe through tentorium	Cerebellum through foramen magnum	Thalamus and hypothalamus through tentorium	Frontal lobe beneath falx cerebri
Etiology	Ipsilateral mass lesion; diffuse brain swelling	Posterior mass lesion	Diffuse brain swelling	Ipsilateral mass lesion
Pathophysiology	Compression CNIII, later midbrain	Compression ventricular outflow, medulla	Compression midbrain	Compression anterior cerebral artery
Presentation	• Decreased consciousness • Ipsilateral dilated pupil → ptosis and lateral deviation • Contralateral hemiparesis	• Neck pain • Vomiting • Decreased consciousness • Cushing's triad	• Decreased consciousness • Small sluggish pupils • Cheyne–Stokes respirations • Posturing	• Contralateral weakness

CN, cranial nerve.

ED EVALUATION

Cranial computed tomography (CT) is the cornerstone of the initial diagnostic evaluation of the severely head injured child. Its purpose is to identify lesions amenable to surgical intervention or identify severe cerebral edema. Important findings include evidence of brain contusion, subdural or epidural hematoma, intracerebral hematoma, diffuse axonal injury, acute brain swelling, pneumocephalus, subarachnoid hemorrhage, midline shift, or cerebral herniation.

Standard Advanced Trauma Life Support (ATLS) protocols apply to all patients with TBI, and attention should be paid to possible associated injuries, given that these patients are unable to communicate effectively (32,22). As many as 60% of patients with sTBI present with serious concomitant injuries (23). The potential for associated cervical spine injury is of particular concern, and patients with major TBI should be presumed to have cervical spine injury. Cervical spine immobilization should be maintained throughout the ED stay, regardless of initial results of cervical spine imaging.

As noted, scrupulous attention must be paid to the presence of hypotension and hypoxia (33). This means identifying visible or occult hemorrhage and aggressively managing hemorrhagic shock. Ongoing hemorrhage clearly complicates attempts at maintaining

CPP in patients with marginal blood pressure. Similarly, respiratory compromise, either from TBI-related hypoventilation or from pulmonary injury must be rapidly addressed. Such concerns are not restricted to the initial resuscitation; secondary insults from hypotension, hyperglycemia, hypocarbia, and hypoxia must be prevented if at all possible (22).

A standard laboratory panel including complete blood count and electrolyte panel is often obtained in multiply injured patients, regardless of the presence of associated injuries. Elevated liver transaminases may alert the clinician to an unrecognized intra-abdominal injury. A full coagulation panel also should be obtained, given that coagulation abnormalities are common and of prognostic importance in patients with sTBI (21).

KEY TESTING

- CT of head
- CBC, electrolytes, coagulation studies
- Imaging for associated injuries (e.g., cervical spine, abdominal trauma)

ED MANAGEMENT

Airway and Breathing: Patients with severe TBI typically require intubation for of loss of airway protective reflexes or due to hypoventilation (Fig. 246.2). A GCS of less than 8 has traditionally been used as an indication for intubation; this is typically performed as rapid sequence orotracheal intubation with in-line cervical spine immobilization.

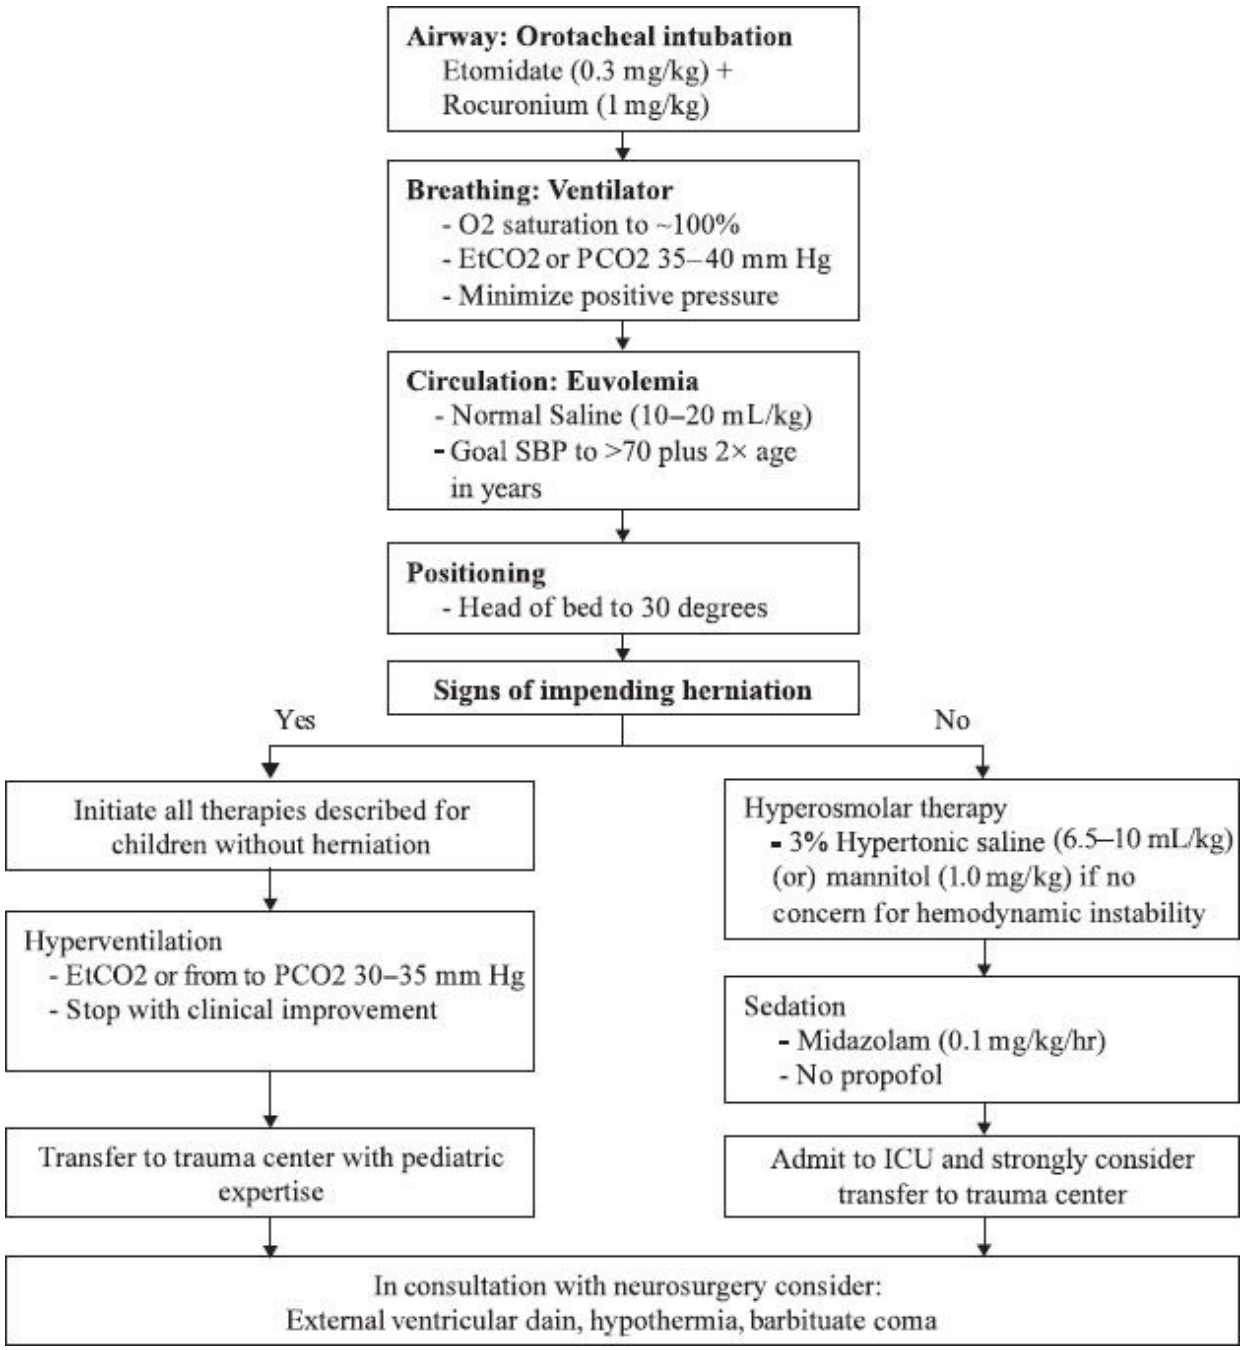

FIGURE 246.2 Emergency management of children with severe traumatic brain injury.

Several adjuncts have traditionally been used to blunt procedurally induced elevations in intracranial pressure in patients with head injury. More recent literature, however, has concluded that their effects in children are not clinically significant. Thus, defasciculation

prior to the use of succinylcholine is no longer considered to be necessary (5,28). Similarly, pretreatment with intravenous lidocaine is no longer recommended (5,28).

Etomidate is an ideal sedative agent, as it has minimal effects on blood pressure and lowers ICP following sTBI (6,28). However, because of concern about adrenal suppression, its use should be limited to a single dose in the ED (6). Thiopental and midazolam have potential neuroprotective effects but can lead to hemodynamic instability. Recent practice guidelines have removed head injury as a relative contraindication to the use of ketamine, which may actually be beneficial in terms of intracranial pressure and cerebral perfusion (8). Recent data suggests the use of ketamine for refractory elevations of ICP or prior to procedural interventions actually *improves* ICP in sedated ICU patients (17).

Ventilator settings should be adjusted to maintain oxygen saturations between 93% and 99%, while minimizing application of positive pressure, which impairs cerebral venous drainage (24). End-tidal carbon dioxide ($EtCO_{2)}$ should be monitored closely. Unless needed for the emergent treatment of acute herniation, hyperventilation should be avoided and $PaCO_2$ maintained between 35 and 40 mm Hg (7,24).

Circulation: Isotonic fluid (normal saline or lactated Ringer's solution) should be administered as necessary to achieve euvolemia. If hypotension persists despite aggressive resuscitation with crystalloid or blood products, vasopressors may be considered.

Positioning: The effect of position on intracranial pressure appears to exhibit interpatient variability and the optimal position may be patient-specific (19). Placement of the head in the midline and elevation of the head of the bed to approximately 30 degrees appear to promote venous drainage and reduce ICP, though with an equivocal effect on CPP (19). Elevation beyond 30 degrees is likely to reduce CPP and should be avoided.

Sedation: Analgesia and sedation can improve ICP by reducing pain and stress. Administration of analgesics and sedatives in small, frequent doses can help to reduce ICP while minimizing hypotension. While there are theoretical benefits to particular agents, none have

been compared empirically. However, reports of increased mortality from metabolic acidosis associated with propofol infusions in critically ill children have led to recommendations against its use in children with TBI (6). Similarly, multiple doses of etomidate are not recommended due to the possibility of adrenal suppression (6). Midazolam (0.1 mg/kg/hr) may be a more appropriate choice in the absence of overt hypotension.

Neuromuscular Blockade: Neuromuscular agents reduce ICP by decreasing airway and intrathoracic pressure, thereby promoting increased cerebral drainage. They also reduce metabolic demand and spikes in ICP by preventing muscle contraction. However, they mask neurologic findings and seizure activity and (except for use in RSI) should only be employed when sedatives do not correct elevations in ICP.

Anticonvulsants: The incidence of early posttraumatic seizures, defined as within 7 days of injury, is approximately 10% in children. Recommendations for prophylactic anticonvulsants are weaker than those in adults, but they may be considered when significant risk factors for posttraumatic seizures, such as depressed skull fracture, penetrating injury, cerebral contusion, or retained fragments, are present.

Hypothermia: Prophylactic hypothermia in the setting of severe pediatric TBI has not been shown to improve outcomes (14,15).

Management of herniation and severely elevated ICP: Aggressive intervention to address severely elevated ICP have been demonstrated to improve outcomes (9).

Interventions such as sedation, paralysis, judicious hyperventilation, hyperosmolar therapy, cerebrospinal fluid drainage, and surgical decompression improve mortality (7). Hypocapnia causes cerebral vasoconstriction, reducing cerebral blood flow, volume, and ICP. This may effectively reverse cerebral herniation as part of an emergent life-saving salvage strategy. However, children with sTBI should not be hyperventilated to a $PaCO_2$ below 30 mm Hg (7).

In children with sTBI, a single episode of $PaCO_2 < 30$ mm Hg in the first 48 hours has been associated with increased mortality (odds

ratio ~ 1.5). Two or more episodes of severe hypocarbia increase the odds ratio to 4 (16). Emergency providers should utilize $EtCO_2$ monitors to ensure that $PaCO_2$ is maintained in an appropriate range of 35 to 40 mm Hg, or 30 to 35 mm Hg during hyperventilation, for impending herniation.

Patients with increased ICP or herniation should receive intravenous mannitol (usual dose 1 gm/kg; recommended administration time 30 minutes). Mannitol, an osmotic diuretic, reduces ICP partly through the immediate reduction of cerebral blood volume (with maintained cerebral blood flow) and intracranial pressure, an effect that lasts less than 75 minutes (30). Mannitol also osmotically draws water from the brain parenchyma into the systemic circulation, reducing intraparenchymal volume and ICP; an effect which lasts up to 6 hours. Mannitol should not be used prophylactically but rather should be reserved for patients manifesting signs of imminent herniation.

Hypertonic saline is an alternative hyperosmolar agent. It appears to reduce ICP through mechanisms similar to those of mannitol, with production of an osmotic gradient across an intact blood–brain barrier (30). It causes less osmotic diuresis and hypotension than mannitol and is preferable for patients with multisystem trauma. While severe hypernatremia (>160 mEq/L) has been associated with poor outcomes in pediatric sTBI, this is unlikely to occur with therapeutic hyperosmolar treatment (26). There is currently insufficient evidence to support the use of saline concentrations greater than 3%, although this issue remains unsettled (26,27). While mannitol has long been the traditional hyperosmolar agent of choice used in the treatment of increased ICP, current recommendations favor the use of hypertonic (3%) saline (30).

CRITICAL INTERVENTIONS

- Early aggressive treatment of hypotension or hypoxia
- Recognition of concomitant traumatic injuries
- Adequate sedation during and after intubation

- Hyperosmolar therapy and mild hyperventilation (PCO_2 30 to 35 mm Hg) for herniation
- Early consultation with neurosurgery or transfer to pediatric trauma center

DISPOSITION

Management of pediatric patients with severe multi-system trauma is clearly associated with improved outcome; this is no different for children who have suffered severe head trauma (4). Admission to a specialized pediatric intensive care unit allows for the early aggressive management that has been demonstrated to improve outcome of sTBI in children.

Common Pitfalls

- Failure to recognize and promptly treat even brief episodes of hypoxemia or hypotension.
- Failure to reassess the neurologic examination frequently to identify signs of increased ICP.
- Failure to consider nonaccidental trauma in infants with TBI, particularly those with subdural hematoma.
- Excessive hyperventilation to $PaCO_2$ <30 mm Hg.
- Failure to consider concomitant injuries, including cervical spine injuries.

CHAPTER 247
Minor Head Trauma

Lois K. Lee and Nathan Kuppermann

CLINICAL PRESENTATION

Blunt head trauma occurs commonly in children 0 to 18 years old, with more than 600,000 children evaluated in US emergency departments (EDs) annually for this complaint. Most children present with minor head trauma, and approximately 90% of children are treated and then discharged home (1). Falls, sports, and motor vehicle crash–related mechanisms are the leading causes of head trauma (1); however, injury mechanism alone is not strongly predictive of traumatic brain injury (TBI). Although severe mechanisms can lead to severe injuries, an isolated severe mechanism of injury ("Key Testing" table), without signs or symptoms of TBI, is not a substantial predictor of clinically important TBI (2). This is defined as TBI resulting in death, neurosurgery, intubation for greater than 24 hours, or hospitalization for two or more nights in association with TBI on CT (3).

The definition of minor head trauma varies in the research literature, but for the purposes of this chapter minor head trauma will be defined as Glasgow Coma Scale (GCS) scores of 14 to 15 after blunt head trauma (Table 247.1) (3,4). Children with minor head trauma can present variably and with a spectrum of symptoms and signs. For example, an infant who falls off a table onto a hard surface can present with a normal mental status and a large scalp hematoma. A school-aged child with head trauma sustained in a motor vehicle crash may present with vomiting and complaints of a headache. An adolescent with head trauma from playing football can present with a history of loss of consciousness (LOC) and may be slow to respond

to questioning. All of these children could meet the definition of minor head trauma on the basis of their GCS scores. The challenge in assessing a child with seemingly minor head trauma in the ED is weighing the immediate risk of clinically important TBI against the long-term risk of exposure to ionizing radiation from emergent cranial CT neuroimaging (5–7). Most earlier studies regarding the evaluation of children with blunt head trauma were characterized by their small sample sizes, retrospective nature, and varied definitions of predictors and outcomes. Recently, however, there have been several large prospective multicenter studies to guide clinicians in the evaluation of these patients.

TABLE 247.1
Pediatric Glasgow Coma Scale (GCS) Score Modified for the Preverbal Child (8)

Eye Opening	
Spontaneous	4
To voice	3
To pain	2
None	1
Verbal Response	
Coos, babbles	5
Irritable cries	4
Cries to pain	3
Moans to pain	2
None	1
Motor Response	
Spontaneous movements	6
Withdraws to touch	5
Withdraws to pain	4
Abnormal flexion	3
Extensor response	2
None	1

Pediatric GCS score: Eye opening + Verbal response + Motor response = 3 to 15

DIFFERENTIAL DIAGNOSIS

Minor head trauma uncommonly results in clinically important TBI. In a large prospective multicenter study of children 0 through 17 years with GCS scores of 14 to 15 after blunt head trauma, only 0.9% had clinically important TBIs (3). Another large population-based study of children with minor head trauma reported that a delayed diagnosis of intracranial hemorrhage occurred rarely after ED evaluation and discharge home (9). Nevertheless, children with seemingly minor head trauma may rarely have a serious intracranial hemorrhage. Such children may initially present with headache and a GCS of 15 and then progress to altered mental status, ultimately requiring emergent neurosurgical intervention (e.g., for an epidural hematoma). Although most children with minor head trauma have no intracranial injury, some may have skull fractures or concussions. The clinician must also remain vigilant for nonaccidental trauma in young, preverbal children (<2 years old) with blunt head trauma (10), as clinical prediction rules for the evaluation of blunt head trauma are not predictive if the history provided by the guardians is not accurate (3,4).

ED EVALUATION

The use of CT in the evaluation of children with blunt head trauma has greatly increased over the past two decades, but appears to have leveled off in recent years (6,11). Although cranial CT is the reference standard for emergently diagnosing TBI, there is a dose- and age-dependent increased lifetime risk of cancer attributable to the ionizing radiation associated with cranial CT scans (5,7). The estimated risks for leukemia range from 1 case per 5,250 scans for children younger than 5 years old to 1 case per 21,160 scans for children 11 to 14 years old; and for solid tumors the risk ranges from 1 tumor per 570 scans for girls younger than 5 years old to 1 solid tumor per 4,660 scans for boys 10 to 14 years old (6). As a result, the decision to evaluate a child with cranial CT imaging after minor head trauma should be considered carefully in the context of the history and physical examination.

The clinician should elicit a thorough history, (3,4) while the physical examination should begin with an overall assessment of the
